CHAPTER 45

Drug-Induced Liver Disease

WILLIAM R. KIRCHAIN AND RONDALL E. ALLEN

KEY CONCEPTS

1. The liver itself through its normally functioning enzymes and processes often causes a drug to become toxic through a process known as bioactivation.
2. Drug-induced liver disease occurs as several different clinical presentations: idiosyncratic reactions, allergic hepatitis, toxic hepatitis, chronic active toxic hepatitis, toxic cirrhosis, and liver vascular disorders.
3. The mechanisms of drug-induced liver disease are diverse, representing many phases of biotransformation, and are susceptible to genetic polymorphism.
4. A fulminant or severe drug-induced reaction within the liver usually involves the immune system and is marked by large scale cell necrosis.
5. The assessment of a possible liver injury caused by drugs should include what is known in the literature, the timing involved, the clinical course, and, always, an exploration for preexisting conditions that may have encouraged the lesion's development.
6. Liver enzyme assays can help to determine if a particular type of liver damage is present.
7. Monitoring for drug-induced liver disease must be tailored to the drug and the patient's potential risk factors.

The number of drugs associated with adverse reactions involving the liver is extensive.[1] One of the more common reasons for the withdrawal of a drug from the marketplace is an elevation of serum concentrations of liver enzymes.[2] Its impact on the pharmaceutical industry has led regulatory agencies to withdraw drugs from the market, restrict the use of certain medications, and issue black box warnings.[3]

Alcohol-induced liver disease is the most common type of drug-induced liver disease. All other drugs together account for less than 10% of patients hospitalized for elevated liver enzymes.[4] Drug-induced liver disease accounts for as much as 20% of acute liver failure in pediatric populations and at least that many of adults with acute liver failure.[5] In approximately 75% of these cases liver transplantation is ultimately required for patient survival.[2] Of patients who required liver transplantation according to the United Network for Organ Sharing, acetaminophen, isoniazid, antiepileptics, and antibiotics collectively account for just over 60% of cases.[6] In a prospective analysis of 1,200 patients admitted to a hospital in South Carolina for liver dysfunction, isoniazid accounted for 21 of 132 cases with various antibiotics and sulfa drugs accounting for another 30 cases.[7] Overall, the reported incidence of drug-induced liver disease is around 1 in 10,000 to 1 in 100,000 patients.[1]

The liver's function affects almost every other organ system in the body, but there are no specific diagnostic tests for drug-induced liver disease or a means to single out an implicated drug. Therefore it is important to know the patterns of drug-related pathology in order to assess adverse reactions when they occur. (1) The liver's normal metabolic outcome is to decrease the reactivity of a drug or toxin, in effect deactivating it. In many of the patterns of damage that this chapter will review, the first step is a net increase in reactivity that results from the normal processes of metabolism in the liver. This now bioactivated compound if left unconjugated or otherwise unbound is free to react in uncontrolled ways within the cell.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

PATTERNS OF DRUG-INDUCED LIVER DISEASE

HEPATOCELLULAR INJURY

Hepatocellular injury is characterized by significant elevations in the serum aminotransferases which usually precede elevations in total bilirubin levels and alkaline phosphatase levels.[8] Most injuries occur within 1 year of initiating the offending agent. Hepatocellular injury can lead to fulminant hepatitis with a corresponding 20% survival rate with supportive care.[9] For those patients who present with the combination of hepatocellular injury and jaundice, there is a 10% mortality rate.[10] Acarbose, allopurinol, fluoxetine, and losartan are capable of causing hepatocellular injury.[8]

(2) Hepatocellular injuries can be further subdivided by specific histologic patterns and clinical presentations. Centrolobular necrosis, steatohepatitis (steatonecrosis), phospholipidosis, and generalized hepatocellular necrosis are each identifiable by particular biopsy results and subtle differences in clinical presentation.

CENTROLOBULAR NECROSIS

(2) Centrolobular necrosis is often a dose-related, predictable reaction; however, it also can be associated with idiosyncratic reactions. Also called direct or metabolite-related hepatotoxicity, centrolobular necrosis is usually the result of the production of a toxic metabolite (Fig. 45–1). The damage spreads outward from the middle of a lobe of the liver.

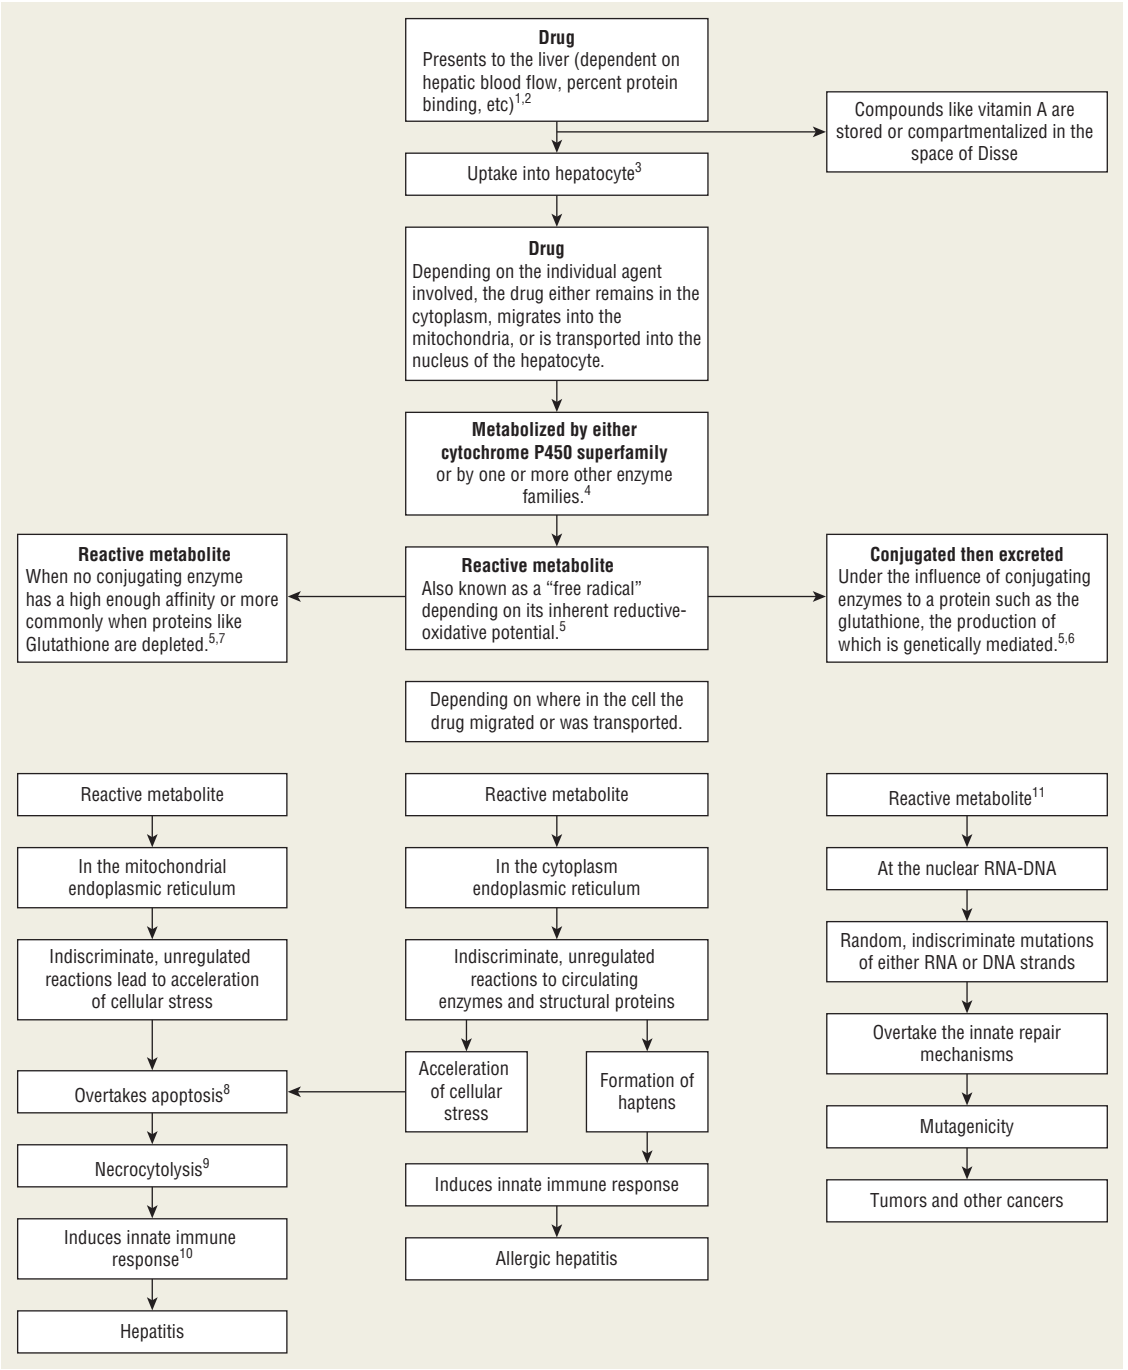

FIGURE 45-1. A general diagram of biotransformation. (1) Hepatic blood flow, which changes proportionately with changes in cardiac output, delivers the drug to the liver. (2) Protein binding is most affected by nutritional status and competing drugs. (3) The drug is actively transported into the hepatocyte by the organic anion transport pump, a transmembrane protein. (4) The metabolite (drug) interacts with one of a number of enzymes, the most common being CYP2C9, 2C19, 2D6, and 3A4. This family of enzymes is regulated by the complementary DNA xenobiotic receptor. The xenobiotic receptor is in turn upregulated by other drugs, changes in cholesterol catabolism, and bile acids. The immediate result of the action of these phase I enzymes is the production of a reactive metabolite. (5) The unstable metabolite then reacts with glucuronidase, various transferases, or hydroxylases to form a conjugated metabolite. The efficacy of these enzymes is affected by the patient's nutritional state and genetic polymorphism, leading to variations in individual risk for toxicity. (6) The conjugated metabolite is removed from the hepatocyte by the canalicular membrane export pump, one of a large family of membrane proteins (other members of this family pump conjugated metabolites back into the blood for excretion by the kidney). These proteins are subject to genetic polymorphism as well, again leading to some patients having an increased risk for toxicity. (7) If unable to form a conjugate, the unstable metabolite can participate in oxidative reactions that damage lipids, proteins, or even DNA. (8) The normal process of cellular aging, death, and reabsorption by surrounding cells. (9) Widespread, rapid cellular death with the creation of multiple antigens. (10) Activation Kupffer cells, killer cells, B-cells, and other T-cells with the associated production of inflammatory cytokines the relative numbers of which and the innate activity of each mediated by genetic polymorphism. (11) Drugs or active metabolites that are transported or diffuse into the mitochondria or the nucleus can damage DNA, leading to mutagenicity and ultimately hepatic cancers.

Patients suffering from centrolobular necrosis tend to present in one of two ways, depending on the extent of necrosis. Mild drug reactions, involving only small amounts of parenchymal liver tissue, may be detected as asymptomatic elevations in the serum aminotransferases. If the reaction is diagnosed at this stage, most of these patients will recover with minimal cirrhosis and thus minimal chronic liver impairment. More severe forms of centrolobular necrosis are accompanied by nausea, vomiting, upper abdominal pain, and jaundice.[11,12]

These reactions are predictable, often dose-related effects in the liver caused by specific agents. When taken in overdose, acetaminophen becomes bioactivated to a toxic intermediate known as *N*-acetyl-*p*-benzoquinone imine (NAPQI). NAPQI is very reactive, with a high affinity for sulfhydryl groups. The protein glutathione provides a ready source of available sulfhydryl groups within the hepatocyte. When the liver's glutathione stores are depleted and there are no longer sulfhydryl groups available to detoxify this metabolite, it begins to react directly with the hepatocyte (see Fig. 45–1). In addition, the depletion of glutathione changes the mitochondrial oxidized to reduced glutathione ratio resulting in catastrophic shifts in mitochondrial function, accelerating cell necrocytolysis.[13] Replenishing the liver's sulfhydryl capacity through the administration of *N*-acetylcysteine early after ingestion of the overdose halts this process.[13] During the first hours after ingestion, some patients report mild symptoms of nausea and vomiting, but no elevations of the commonly measured liver enzymes are seen. Serum elevations in the liver enzymes begin 40 to 50 hours after ingestion.[14]

Reye syndrome is an aggressive form of toxic hepatitis often associated with aspirin use in children. Valproate toxicity can also present in this pattern. Early in the process of Reye syndrome, mitochondrial dysfunction leads to the depletion of acyl-coenzyme A and carnitine. Fatty acids accumulate and gluconeogenesis is impaired, resulting in hypoglycemia. A concurrent disruption of the urea cycle occurs, leading to a decrease in the removal of ammonia and a slowing of protein use. A threefold rise in the blood ammonia level and an increase in the prothrombin time are common findings. In advanced stages of Reye's syndrome, many patients develop intracranial hypertension that can be life-threatening and refractory to therapy.[15,16]

NONALCOHOLIC STEATOHEPATITIS

Nonalcoholic steatohepatitis (NASH), also known as steatohepatitis and steatonecrosis, results from the accumulation of fatty acids in the hepatocyte. In the pre-acute stages this is known as nonalcoholic fatty liver disease (NAFLD). Drugs or their metabolites that cause NAFLD do so by affecting fatty-acid esterification and oxidation rates within the mitochondria of the hepatocyte (see Fig. 45–1). Hepatic vesicles become engorged with fatty acids, eventually disrupting hepatocyte homeostasis. In patients with diabetes, various dyslipidemias and even hypertension, the de novo production of free fatty acids from excess circulating carbohydrates, accelerates this process of accumulation. The liver biopsy is marked by a massive infiltration by polymorpho-nuclear leukocytes, degeneration of the hepatocytes, and the presence of Mallory bodies.[4]

Alcohol is the drug that most commonly produces steatonecrotic changes in the liver. When alcohol is converted into acetaldehyde, the synthesis of fatty acids is increased.[17,18] The hepatocyte can become completely engorged with microvesicular fat, resulting in alcoholic fatty liver. Metabolically this type of de novo free fatty acid synthesis depletes NADPH in favor of $NADP^+$ and reduces the hepatocytes' ability to respond to stress, bypassing normal apoptosis and increasing the rate of necrocytolysis. In NAFLD, the same end point is often achieved through oxidation of lipid peroxidases.[19] If the offending agent is withdrawn before significant numbers of hepatocytes become necrotic, the process is completely reversible without long-term sequelae. If not, then ever increasing rates of necrocytolysis will induce an innate immune response and result in hepatitis.

Tetracycline produces NAFLD and NASH.[20] The lesions are characterized by large vesicles of fat found diffused throughout the liver. The development of this reaction is related to the high concentrations achieved when tetracycline is given intravenously and in doses greater than 1.5 g/day. The mortality of tetracycline steatohepatitis is high (70%–80%), and those who do survive often develop cirrhosis. Sodium valproate also can produce steatonecrosis through the process of bioactivation. 1 Cytochrome P450 converts valproate to delta-4-valproic acid, a potent inducer of microvesicular fat accumulation.[21]

Patients experiencing steatohepatitis may present with abdominal fullness or pain as their only complaint. Patients with more severe steatonecrosis will present with all the symptoms characteristic of alcoholic hepatitis such as nausea, vomiting, steatorrhea, abdominal pain, pruritus, and fatigue.

PHOSPHOLIPIDOSIS

Phospholipidosis is the accumulation of phospholipids instead of fatty acids. The phospholipids usually engorge the lysosomal bodies of the hepatocyte.[22] Amiodarone is associated with this reaction. Patients treated with amiodarone who develop overt hepatic disease tend to have received higher doses of the drug. These patients also have higher amiodarone-to-*N*-desethyl-amiodarone ratios, indicating a greater accumulation of the parent compound. Amiodarone and its major metabolite *N*-desethyl-amiodarone remain in the liver of all patients for several months after therapy is stopped. Usually the phospholipidosis develops in patients treated for more than 1 year. The patient can present with either elevated aminotransferases or hepatomegaly; jaundice is rare.[4,23]

GENERALIZED HEPATOCELLULAR NECROSIS

Generalized hepatocellular necrosis mimics the changes associated with the more common viral hepatitis. The onset of symptoms is usually delayed as much as a week or more after exposure to toxin. Bioactivation is often important for toxic hepatitis to develop. Many drugs that are associated with toxic hepatitis produce metabolites that are not inherently toxic to the liver. Instead, they bind with proteins to create haptens, which serve as neoantigens and induce the innate immune response (see Fig. 45–1).[24]

1 The rate of bioactivation can vary between males and females and between individuals of the same sex.[25,26] The superfamily of cytochrome P450 (CYP450) enzymes metabolize lipophilic substrates that are actively pumped into the hepatocyte by an organic anion (or cation) transporting protein. The CYP450 subspecies 2C, 2D, 3A, and 4A are regulated by the highly inducible xenobiotic receptor on complementary DNA. The receptor is found in the liver, and to a lesser extent in the cells lining the intestinal tract, and is responsible for cholesterol catabolism and bile acid homeostasis. 3 The activity of this receptor is subject to genetic polymorphism. This results in a wide variation in the sensitivity of the population to hepatic damage.[27]

The long-term administration of isoniazid can lead to hepatic dysfunction in 10% to 20% of those receiving the drug. Yet severe toxic hepatitis develops in only 1% or less of this population.[28] 3 The *N*-acetyltransferase 2 (NAT2) genotype appears to play a role in determining a patient's relative risk. In one study, patients with the slow-type NAT2 genotype had a 28-fold greater risk of developing serum aminotransferase elevations than did patients with the fast-type NAT2 genotype.[29] Isoniazid is metabolized by several pathways, acetylation being the major pathway. It is acetylated to

acetylisoniazid, which, in turn, is hydrolyzed to acetylhydrazine.[30] The acetylhydrazine, and to a lesser extent the acetylisoniazid, are directly toxic to the cellular proteins in the hepatocyte, but rapid acetylators detoxify acetylhydrazine very rapidly, converting it to diacetylhydrazine (a nontoxic metabolite). Therefore, it is the rate and efficiency of this reaction sequence that ultimately determines if hepatocellular damage will ensue.

Isoniazid simultaneously is an example of the potential predictability of drug-induced liver disease based on single nucleotide polymorphism and a lesson in the limitations of our current understanding. 3 There are definite links to NAT2 genotype and toxicity.[31] The risk for this reaction is also influenced heavily by the age of the patient, with older patients having a much higher risk than younger patients. In fact, age may be more important than genotype.[28,29,31] In one prospective series focused on drug-induced liver disease, cases involving isoniazid had a median onset at 6 months of therapy with around 30% of isoniazid-induced liver disease clustered between 6 to 8 months.[7]

Ketoconazole produces generalized hepatocellular necrosis or milder forms of hepatic dysfunction in 1% to 2% of patients treated for fungal infections. The onset is usually early in therapy. In immunocompromised patients in whom ketoconazole is used, special care should be taken to watch for changes in liver function.[32]

TOXIC CIRRHOSIS

The scarring effect of hepatitis in the liver leads to the development of cirrhosis. Some drugs tend to cause such a mild case of hepatitis that it may not be detected. Mild hepatitis can be easily mistaken for a more routine generalized viral infection. If the offending drug or agent is not discontinued, this damage will continue to progress. The patient eventually presents not with hepatitis, but with cirrhosis.

Methotrexate causes periportal fibrosis in most patients who experience hepatotoxicity. 1 The lesion results from the action of a bioactivated metabolite produced by CYP450.[33] This process occurs most commonly in patients treated for psoriasis and arthritis. The extent of damage can be reduced or controlled by increasing the dosage interval to once weekly or by routine use of folic acid supplements.[33] Vitamin A is normally stored in liver cells, and causes significant hypertrophy and fibrosis when taken for long periods in high doses. Hepatomegaly is a common finding, along with ascites and portal hypertension. In patients with vitamin A toxicity, gingivitis and dry skin are also very common. This is accelerated by ethanol, which competes with retinol for aldehyde dehydrogenase.[17]

CHOLESTATIC INJURY

2 A second pattern of hepatic damage is an injury that primarily involves the bile canalicular system and is known as cholestatic injury. Cholestatic disease is more often seen in patients over the age of 60 and is slightly more common in males.[34] In cholestatic disease, disturbance of the subcellular actin filaments around the canaliculi prevents the movement of bile through the canalicular system.[35] The inability of the liver to remove bile causes intrahepatic accumulation of toxic bile acids and excretion products.[36] Although rare, some patients develop progressive destruction of the cholangiocytes leading to the vanishing bile duct syndrome.

Drug-induced cholestasis can occur as an acute disorder (e.g., cholestasis with or without hepatitis and cholestasis with bile duct injury) or as a chronic disorder (e.g., vanishing bile duct syndrome, sclerosing cholangitis, and cholelithiasis).[37] However, the most common form of drug-induced cholestasis is cholestasis with hepatitis. Most patients with this acute disorder present with nausea, malaise, jaundice, and pruritus.[8] Elevations in serum alkaline phosphatase levels are more prominent and usually precede the elevations of other liver enzymes in serum.[5] A liver biopsy is not usually required, but is sometimes pursued when other causes of cholestatic disease are suspected.[38] Although the antipsychotic drug chlorpromazine appears to be the prototype drug for this disorder, other medications are associated with other forms of cholestatic injury, such as erythromycin estolate, amoxicillin-clavulanic acid, and carbamazepine.[9]

Cholestatic injury, also known as cholestatic jaundice or cholestasis, can be classified by the area of the bile canalicular or ductal system that is impaired. Canalicular cholestasis is often associated with long-term, high-dose estrogen therapy. These patients are often asymptomatic and present with mild to moderate elevations of serum bilirubin.[39] An intravenous form of vitamin E, α-tocopherol acetate, causes cholestatic jaundice, primarily involving the canalicular duct in premature infants. The incidence of this reaction in those receiving this formulation was high (>10%) and the mortality even higher (>50%).[40]

The administration of total parenteral nutrition for periods greater than 1 week induces cholestatic changes and nonspecific enzyme elevations in some patients. Patients with low serum albumin concentrations may be at greater risk than patients with normal serum albumin concentrations.[4] This reaction also has been reported to occur rarely with sulfonamides, sulfonylureas, erythromycin estolate and ethylsuccinate, captopril, lisinopril, and other phenothiazines.[41]

MIXED HEPATOCELLULAR AND CHOLESTATIC INJURY

1 The final pattern of hepatic damage is a combining of the previous two patterns. This presentation can be the result of three different processes. In some patients, an injury may begin as hepatocellular (or cholestatic) and simply spread so rapidly that by the time the patient presents for diagnosis and treatment, all areas of the liver are affected. In other patients, the underlying mechanism of damage is such that cells are injured regardless of their anatomical location or primary metabolic role.

LIVER VASCULAR DISORDERS

Focal lesions in hepatic venules, sinusoids, and portal veins occur with various drugs. The most commonly associated drugs are the cytotoxic agents used to treat cancer, the pyrrolizidine alkaloids, and the sex hormones. A centralized necrosis often follows and can result in cirrhosis. Azathioprine and herbal teas that contain comfrey (a source of pyrrolizidine alkaloids) are associated with the development of venoocclusive disease. The exact incidence is rare and may be dose related.[4] Peliosis hepatitis is a rare type of hepatic vascular lesion that can be seen as both an acute and a chronic disease. The liver develops large, blood-filled lacunae (space or cavity) within the parenchyma. Rupture of the lacunae can lead to severe peritoneal hemorrhage. Peliosis hepatitis is associated with exposure of the liver to androgens, estrogens, tamoxifen, azathioprine, and danazol. Androgens with a methyl alkylation at the 17-carbon position of the testosterone structure are the most frequently reported agents that cause peliosis hepatitis, usually after at least 6 months of therapy.[42]

MECHANISMS OF DRUG-INDUCED LIVER DISEASE

STIMULATION OF AUTOIMMUNITY

4 Autoimmune injuries involve antibody mediated cytotoxicity or direct cellular toxicity.[38,43] This type of injury occurs when enzyme drug adducts migrate to the cell surface and form neoantigens. The

liver plays host to all of the cells that make up the innate immune response system in the body along with Kupffer cells which are a type of macrophage. These cells sit in anticipation around the hepatocytes, in the space of Disse and elsewhere waiting for antigens (or neoantigens) to present themselves. The neoantigens serve as targets for cytolytic attack by killer T-cells, and others.[7] Halothane, sulfamethoxazole, carbamazepine, and nevirapine are associated with autoimmune injuries.[35] Stimulation of autoimmunity is often associated with fulminant presentations.

Dantrolene, isoniazid, phenytoin, nitrofurantoin, and trazodone are associated with a type of autoimmune-mediated disease in the liver called *chronic active hepatitis*.[11] Patients experience periods of symptomatic hepatitis followed by periods of convalescence, only to repeat the experience months later. It is a progressive disease with a high mortality rate and is more common in females than males. Antinuclear antibodies appear in most patients. These drugs appear to form antiorganelle antibodies.[23] The exact identification of a causative agent is sometimes difficult as diagnosis requires multiple episodes occurring long after exposure to the offending drug.

IDIOSYNCRATIC REACTIONS

Idiosyncratic drug-related hepatotoxicity is rare and usually occurs in a small proportion of individuals. These adverse reactions are often categorized into allergic and nonallergic reactions. 4 The allergic reactions are characterized by fever, rash, and eosinophilia. They are usually dose-related and have a short latency period (<1 month). Upon reexposure to the offending agent, the patient will experience rapid recurrence of hepatotoxicity. Studies show that minocycline, nitrofurantoin, and phenytoin can cause allergic reactions.[3]

Unlike the allergic reactions, the nonallergic idiosyncratic reactions are devoid of the hypersensitivity features and usually have a long latency period (several months). These patients often have normal liver function tests for 6 months or longer and then suddenly develop hepatotoxicity. Dependent on the medication, the incident can be independent of dose or dose related. Amiodarone, isoniazid, and ketoconazole are associated with nonallergic drug-related hepatotoxicity.[3]

DISRUPTION OF CALCIUM HOMEOSTASIS AND CELL MEMBRANE INJURY

Drug-induced damage to the cellular proteins that are involved with calcium homeostasis can lead to an influx of intracellular calcium that causes a decline in adenosine triphosphate levels and disruption of the actin fibril assembly. The resulting impact on the cell is blebbing of the cell membrane, rupture, and cell lysis.[36] Lovastatin, venlafaxine, and phalloidin, which is the active component of mushrooms, impair calcium homeostasis.[36,43]

METABOLIC ACTIVATION OF THE CYTOCHROME P450 ENZYMES

Most hepatocellular injuries involve the production of high-energy reactive metabolites by the CYP450 system. These reactive metabolites are capable of forming covalent bonds with cellular proteins (enzymes) and nucleic acids that lead to adduct formation. In the case of acute toxicity, the enzyme-drug adduct can cause cell injury or cell lysis. Adducts that form with DNA can cause long-term consequences such as neoplasia. Acetaminophen, furosemide, and diclofenac are examples of this mechanism of liver injury.[44] Individual genetic differences can play a role in the significance of this process. Patients with a single nucleotide polymorphism (SNP) that codes for slow-reacting variants of CYP450 will react differently from those with a SNP that codes for very fast-reacting variants.

STIMULATION OF APOPTOSIS

Apoptosis represents a distinct pattern of cell lysis that is characterized by cell shrinkage and fragmentation of nuclear chromatin. Apoptotic pathways are triggered by interactions between death ligands (tumor necrosis factor and Fas ligand) and death receptors (tumor necrosis factor receptor 1 and Fas). These interactions activate caspases which cleave cellular proteins and eventually lead to cell death.[45] Cumulative doses of acetaminophen cause apoptosis.[43]

MITOCHONDRIAL INJURY

Drugs that impair mitochondrial structure, function, or DNA synthesis can disrupt β-oxidation of lipids and oxidative energy production within the hepatocyte.[35] In acute disease, prolonged interruption of β-oxidation leads to microvesicular steatosis, whereas, in chronic disease, macrovesicular disease is present.[9] Severe damage to the mitochondria eventually leads to hepatic failure and death. Aspirin, valproic acid, and tetracycline cause mitochondrial injury by inhibiting β-oxidation and amiodarone via disruption of oxidative phosphorylation.[36]

LIVER NEOPLASTIC DISEASE

A large body of the current literature on adverse reactions and the liver addresses the development of neoplasms following drug therapy. Both carcinoma- and sarcoma-like lesions have been identified. Fortunately, hepatic tumors associated with drug therapy are usually benign and remit when drug therapy is discontinued. Except in rare instances, these lesions are associated with long-term exposure to the offending agent.[46] Androgens, estrogens, and other hormonal-related agents are the most frequently associated causes of neoplastic disease. The model for drug-induced hepatic cancer is polyvinyl chloride exposure. Used in the production of many types of plastic products, polyvinyl chloride induces angiosarcoma in exposed workers after as few as 3 years of exposure.[47]

ASSESSMENT

The best and most important technique for assessing and monitoring drug-induced liver disease is the patient's history. 5 Questions addressing the patient's drug use along with a thorough review of systems are essential. The use of a protocol, such as that proposed by Danan and Benichou, can significantly improve the accuracy of the assessment (Table 45–1).[48] Drugs for recreational purposes must not be overlooked. Cocaine has been directly linked to liver disease.[49] Ecstasy, the street name of methylenedioxymethamphetamine, has induced fulminant hepatitis, which has led to death in some cases.[50] The more pervasive impact of street drugs on the incidence of hepatic disease is the concomitant injection or ingestion of adulterants. Many of these adulterants are either directly toxic or serve to enhance the toxicity of the drug.

It is also important to determine nondrug hepatic disease risk from occupational or environmental exposure. Arsenic, for example, is known to induce both acute and chronic hepatic reactions.[50] Even if exposure to an environmental toxin does not produce a hepatic reaction, it may predispose a patient to a hepatic reaction when a drug is added. Table 45–2 lists some of the more common hepatic toxins found in occupational or environmental exposures that can add to the risk for developing a hepatic lesion.[51] Immune-mediated chronic liver diseases can often be tracked to geographic clusters that correspond to known toxic waste sites around the world.[51]

TABLE 45-1 An Approach to Evaluating a Suspected Hepatotoxic Reaction Using a Clinical Diagnostic Scale

Patient Presents with Elevated Liver Enzymes	Score	Component Subscore
Literature		
Literature supports this drug (drug combination) and pattern of liver enzyme elevation	+2	
No literature supports this, but the drug has been on the market less than 5 years	+0	–
No literature supports this and the drug has been on the market for 5 years or more	–3	
Alternative causes		
Alternative causes (e.g., viral, alcohol) are completely ruled out	+3	
Alternative causes are partially ruled out	+0	–
Alternative causes cannot be ruled out and are possible or even probable	–1	
Presentation		
The presentation includes 4 or more extrahepatic (fever, malaise, etc.) symptoms	+3	
The presentation includes 2–3 extrahepatic symptoms	+2	–
The presentation includes only 1 identifiable extrahepatic symptom	+1	
The presentation is essentially a laboratory abnormality, with no extrahepatic symptoms	+0	
Temporality		
Initiation of drug therapy to onset is 4–56 days	+3	
Initiation of drug therapy to onset is <4 or >56 days	+1	
Discontinuance of therapy to onset is 0–7 days	+3	–
Discontinuance of therapy to onset is 8–15 days	+0	
Discontinuance of therapy to onset is >15 days	–1	
Rechallenge		
Rechallenge was positive	+3	–
Rechallenge was negative or not attempted	+0	
Total Score		–

The likelihood that this presentation is an adverse reaction in the liver increases linearly with an increasing score. The maximum score is 14, and scores below 7 are associated with an ever decreasing likelihood that the drug or drug combination in question caused the problem. This approach is not designed for the assessment of hepatic cancers or cirrhotic conditions.

Reprinted from J Clin Epidemiol, Vol 46, Danan G, Benichou C. Causality assessment of adverse reactions to drugs–I. A novel method based on the conclusions of international consensus meetings: Application to drug-induced liver injuries: pages 1323–1330, Copyright 1993, with permission from Elsevier.

A person's use of alternative medicine must be solicited. In the prospective series of cases noted earlier, from an area of the country where traditional medicine usage is commonplace, herbal remedies and other traditional medicines accounted for 14 of 132 cases of drug-induced liver disease.[7] Comfrey tea is a common cause of hepatocellular damage. As in the case of the Chinese remedy *jin bu huan*, or as in the case of the more elegantly presented chaparral capsules containing grease wood leaves, the end of therapy with these types of agents is occasionally severe disability or death from fulminant hepatic failure.[52] Pennyroyal oil, margosa oil, and clove oil cause a dose-related hepatotoxicity.[52]

TABLE 45-2 Environmental Hepatotoxins and Associated Occupations at Risk for Exposure

Hepatotoxin	Associated Occupations at Risk for Exposure
Arsenic	Chemical plant, agricultural workers
Carbon tetrachloride	Chemical plant workers, laboratory technicians
Copper	Plumbers, sculpture artists, foundry workers
Dimethylformamide	Chemical plant workers, laboratory technicians
2,4-Dichlorophenoxyacetic acid	Horticulturists
Fluorine	Chemical plant workers, laboratory technicians
Toluene	Chemical plant, agricultural workers, laboratory tech
Trichloroethylene	Printers, dye workers, cleaners, laboratory technicians
Vinyl chloride	Plastics plant workers; also found as a river pollutant

The nutritional status of a patient can be as important to the development of a drug-induced liver disease as the hepatotoxin itself.[50] Patients who are malnourished because of illness or long-term alcohol abuse make up the most troublesome group.[53] Low serum levels of vitamins E and C, along with lutein and the α- and β-carotenes are associated with asymptomatic elevations in transaminases. Conversely, high serum iron, transferrin, and selenium levels are also associated with asymptomatic elevations of transaminases.[54]

All potential drug reactions should be judged as to the timing of the reaction versus drug administration, pharmacokinetic considerations, the information in the literature records about previous reactions, the inclusion of alternative nondrug causes, and close clinical observation when the drug in question is stopped. It is also important to keep in mind that most elevations in liver enzymes will not be associated with a drug. In a study of all patients admitted to a hospital in the United Kingdom with elevated liver aminotransferases, only 9% of cases involved a drug other than alcohol as the possible cause.[3] In all cases, titers of serum antibodies to hepatitis A, B, and C should be drawn. Even in cases in which the drug is absolutely targeted as the cause, viral hepatitis may be a complication.

Often there is no good clinical test available to determine the exact type of hepatic lesion, short of liver biopsy. 6 There are certain patterns of enzyme elevation that have been identified and can be helpful (Table 45–3).[55,56] The specificity of any serum enzyme depends on the distribution of that enzyme in the body. Alkaline phosphatase is found in the bile duct epithelium, bone, and intestinal and kidney cells. 5′-Nucleotidase is more specific for hepatic disease than alkaline phosphatase, because most of the body's store of 5′-nucleotidase is in the liver. Glutamate dehydrogenase is a good indicator of centrolobular necrosis because it is found primarily in centrolobular mitochondria. Most hepatic cells have extremely high concentrations of transaminases. Aspartate aminotransferase (AST) and alanine aminotransferase (ALT) are commonly measured in serum. Because of their high concentrations and easy liberation from the hepatocyte cytoplasm, AST and ALT are sensitive indicators of necrotic lesions within the liver. After an acute hepatic lesion is established, it may take weeks for these concentrations to return to normal.[56]

Serum bilirubin concentration is a sensitive indicator of most hepatic lesions and has significant prognostic value. High peak bilirubin concentrations are associated with poor survival. Other important findings that indicate poor survival are a peak prothrombin time greater than 40 seconds, elevated serum creatinine, and low arterial pH. The presence of encephalopathy or prolonged jaundice are not good signs for the survival of the patient and are strong indicators for transplantation.[57]

Bilirubin concentrations and serum enzyme elevations give a static picture of the liver's condition and are not good indicators of hepatic function. Clinically available tests to predict hepatic function include measurement of serum proteins (albumin or transferrin). As a hepatic function decreases, serum protein concentrations in the body decrease at a rate determined by each protein's own elimination rate. Overhydration and starvation can also decrease serum protein concentrations. Changes in the prothrombin time often occur earlier than the changes in albumin or transferrin. The response of the prothrombin time to the administration of 10 mg of parenteral vitamin K is often used to differentiate between hepatic and extrahepatic disease.

TABLE 45-3 Relative Patterns of Hepatic Enzyme Elevation versus Type of Hepatic Lesion

Enzyme	Abbreviations	Necrotic	Cholestatic	Chronic
Alkaline phosphatase	Alk Phos, AP	↑	↑↑↑	↑
5′-Nucleotidase	5-NC, 5NC	↑	↑↑↑	↑
γ-Glutamyltransferase	GGT, GGTP	↑	↑↑↑	↑↑
Aspartate aminotransferase	AST, SGOT	↑↑↑	↑	↑↑
Alanine aminotransferase	ALT, SGPT	↑↑↑	↑	↑↑
Lactate dehydrogenase	LDH	↑↑↑	↑	↑

↑, <100% of normal; ↑↑, >100% of normal, ↑↑↑, >200% of normal.

MEASUREMENT OF LIVER FUNCTION

A good compound for a liver function test would theoretically be (a) nontoxic and lacking any pharmacologic effect; (b) either rapidly and completely absorbed orally or easily administered via a peripheral vein; (c) eliminated only by the liver; and (d) easily measured (drug and its metabolite) in blood, saliva, or urine.[58]

Several tests are used in research settings and in liver transplant patients to indicate liver function. Tests such as sulfobromophthalein, indocyanine green, or sorbitol measure qualities of hepatic clearance. There are also a few drugs that have been used to test liver function. The advantage of sorbitol over indocyanine green is a much lower incidence of allergic reactions. It is partially cleared by the kidney, and urine levels must also be determined during the test.[58] A good estimate of hepatic clearance can be obtained by serial blood levels of a variety of hepatically eliminated drugs if an assay is locally available. Ultrasound and computed tomographic imaging can be used on a periodic basis to monitor for the development of fibrosis or vascular lesions in the liver and for hepatocellular carcinomas.[60]

If a liver biopsy has been performed, the injury should be classified by the histologic findings. 6 In cases in which there is no biopsy, the pattern of liver enzyme elevation can estimate the type of injury. Hepatocellular injuries are marked by elevations in transaminase that are at least two times normal. If the alkaline phosphatase is also elevated, a hepatocellular lesion is still suspected when the elevation of ALT is notably higher than the elevation of alkaline phosphatase. If the magnitude of elevation is nearly equal between ALT and alkaline phosphatase, the lesion is likely cholestatic.

A liver injury is acute if it lasts less than 3 months; it is considered chronic after 3 months of consistent symptoms or enzyme elevation. A liver injury is severe if the patient has marked jaundice, if the prothrombin time does not improve by more than 50% after the administration of vitamin K, or if encephalopathy is detectable. If an acute liver injury progresses from normal to severe in a matter of a few days or weeks, it is considered fulminant.[61,62]

MONITORING

The serum transaminases AST and ALT are the most commonly used transaminases in the clinical setting. There are often no set rules available for a particular drug. 7 The general guidelines found in Table 45–4 can help in determining a monitoring schedule for drugs where no prior recommendations are published. Concentrations of these enzymes should be obtained approximately every 4 weeks, depending on the reported characteristics of the reaction in question. Methotrexate should be monitored every 4 weeks, because toxicity usually develops over a period of several weeks to months.[60] In addition, some recommend that sulfobromophthalein or indocyanine green excretion studies be performed on a regular basis and that patients treated for very long periods of time should have a liver biopsy performed every 12 months.[63]

ABBREVIATIONS

ALT: alanine aminotransferase

AST: aspartate aminotransferase

CYP450: cytochrome P450 liver enzyme system

NAFLD: nonalcoholic fatty liver disease

TABLE 45-4 An Approach to Determining a Drug-Monitoring Plan to Detect Hepatotoxicity in Patients Initiated on Hepatotoxic Drugs

Draw a baseline set of blood samples for liver enzymes, bilirubin, and albumin before beginning the drug

↓

Is the patient pregnant?
Is the patient older than age 60 years?
Is the patient exposed to an environmental hepatotoxin at work or at home?
Is the patient drinking more than one alcoholic beverage per day or bingeing?
Is the patient using any injected recreational drug?
Is the patient using herbal remedies or tisanes that are associated with hepatic damage?
Is the patient's diet deficient in magnesium, vitamin E, vitamin C, or α- or β-carotenes?
Is the patient's diet excessive in vitamin A, iron, or selenium?
Does the patient have hypertriglyceridemia or type 2 diabetes mellitus?
Does the patient have juvenile arthritis or systemic lupus erythematosus?
Does the patient have chronic or chronic remitting viral hepatitis (hepatitis B or C)?

↓

Yes to one to two risk factors	No
↓	↓
Redraw liver enzymes every 180 days depending on the drug, for the first year	Redraw liver enzymes if other signs or symptoms manifest

Does the patient have more than two risk factors?
Is the drug identified as one that may cause a predictable hepatotoxic reaction?[a]

Yes	No	No
↓	↓	↓
Redraw liver enzymes every 60–90 days depending on the drug, for the first year	Redraw liver enzymes every 180 days as directed above for the first year	Redraw liver enzymes if other signs or symptoms manifest

If no toxicity is manifested during the first year of therapy, then redraw liver enzymes every 6–12 months; assess liver for cirrhosis every 1–2 years by ultrasound and every 4–6 years by CT or MRI scan; biopsy as directed by other findings

[a]A drug can become a predictable risk if it is administered concurrently with another drug or food that is known to induce or inhibit its metabolism.

NAPQI: *N*-acetyl-*p*-benzoquinone imine

NASH: nonalcoholic steatohepatitis

NAT2: *N*-acetyltransferase 2 genotype

SNP: single nucleotide polymorphism

CHAPTER 46

Pancreatitis

SCOTT BOLESTA AND PATRICIA A. MONTGOMERY

KEY CONCEPTS

ACUTE PANCREATITIS

1. Patients with severe acute pancreatitis require early and aggressive intravenous fluid resuscitation and should be managed similarly to patients with sepsis.
2. Factors that can contribute to acute pancreatitis should be corrected, including discontinuation of medications that could be potential causes.
3. Parenteral opioid analgesics are used to control abdominal pain associated with acute pancreatitis.
4. Meperidine is not recommended as a first-line agent for the treatment of pain from acute pancreatitis due to the risk of adverse effects and the resultant dosing limitations.
5. The only definitive indication for antibiotic use in acute pancreatitis is to treat known or suspected infection.

CHRONIC PANCREATITIS

6. Chronic pain, malabsorption with resultant steatorrhea, and diabetes mellitus are the hallmark complications and symptoms of chronic pancreatitis.
7. Pain from chronic pancreatitis can initially be treated with nonopioid analgesics, but opioids will eventually be required as the disease progresses.
8. Pancreatic enzyme supplementation and reduction in dietary fat intake are the primary treatments for malabsorption due to chronic pancreatitis.
9. Enteric-coated pancreatic enzyme supplements are the preferred dosage form in the treatment of malabsorption and steatorrhea due to chronic pancreatitis.
10. The addition of an antisecretory agent to pancreatic enzyme supplementation may increase the effectiveness of enzyme therapy for malabsorption and steatorrhea due to chronic pancreatitis.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

Pancreatitis is inflammation of the pancreas with variable involvement of regional tissues or remote organ systems.[1] Acute pancreatitis is characterized by severe pain in the upper abdomen and elevations of pancreatic enzymes in the blood.[1–3] In the majority of patients, acute pancreatitis is a mild, self-limiting disease that resolves spontaneously without complications. Approximately 20% of adults have a severe course, and 10% to 30% of those with severe acute pancreatitis die.[1] Although exocrine and endocrine pancreatic function may remain impaired for variable periods after an attack, acute pancreatitis seldom progresses to chronic pancreatitis.[1,2]

Chronic pancreatitis is characterized by long-standing inflammation that eventually leads to a loss of pancreatic exocrine and endocrine function.[4–6] It is a progressive disease that often goes unnoticed for many years. Usually patients first present with complaints of chronic abdominal pain. Later in the disease process malabsorption with resultant steatorrhea occurs. This leads to malnutrition and weight loss. Finally, patients develop diabetes mellitus due to a loss of pancreatic endocrine function.[4,5]

EPIDEMIOLOGY

The prevalence of pancreatitis varies widely with geographic, etiologic (e.g., alcohol consumption), environmental, and genetic factors. The reported prevalence of acute pancreatitis among men and women in the United States is less than 1%.[7] Approximately six per 100,000 population will develop chronic pancreatitis with a peak incidence between ages 35 and 54 and about 85% of cases occurring in men.[6] However, this incidence may be underestimated due to diagnostic difficulties and various classification systems. Also, the prevalence of chronic pancreatitis varies widely based on geographic location.[4,6] Hospitalizations for acute pancreatitis have increased in the United States, most likely related to an increase in gallstones in association with obesity.[8] The incidence of gallstone-related acute pancreatitis has increased among white women older than age 60 years.[9] Hospitalization for chronic pancreatitis has also doubled in the past decade, with black patients being almost two to three times as likely to be hospitalized for chronic pancreatitis than for alcoholic cirrhosis.[6]

PANCREATIC EXOCRINE PHYSIOLOGY

The pancreas possesses both endocrine and exocrine functions. The islets of Langerhans, which contain the cells of the endocrine pancreas, secrete insulin, glucagon, somatostatin, and other polypeptide hormones. The exocrine pancreas is composed of acini and ductules that secrete about 2.5 L/day of isotonic fluid that contains water, electrolytes, and pancreatic enzymes necessary for digestion. Bicarbonate and other electrolytes are secreted primarily by

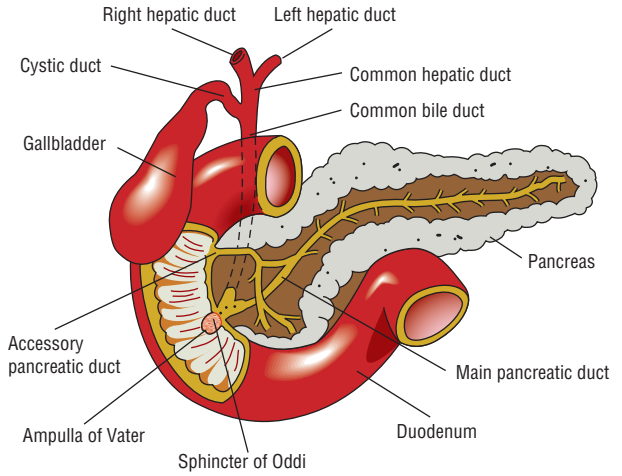

FIGURE 46-1. Anatomic structure of the pancreas and biliary tract.

the centroacinar (ductular) cells in order to neutralize gastric acid. Pancreatic juice is delivered to the duodenum via the pancreatic ducts (Fig. 46–1) where the alkaline secretion neutralizes gastric acid and provides an appropriate pH for maintaining the activity of pancreatic enzymes.[10]

The major pancreatic exocrine enzyme groups are as follows:

- Amylolytic: amylase
- Lipolytic: lipase, procolipase, prophospholipase A_2, and carboxylesterase
- Proteolytic: trypsinogen, chymotrypsinogen, procarboxypeptidase, and proelastase
- Nucleolytic: ribonuclease, deoxyribonuclease
- Other: trypsin inhibitor

Amylase is responsible for digestion of starches and glycogen through hydrolysis. The lipolytic enzymes break down triglycerides, cholesterol, and other fats in the digestive tract. Specifically, lipase hydrolyzes triglycerides into fatty acids and monoglycerides. Colipase and bile acids facilitate this process by allowing lipase to act on the hydrophobic surface of fat droplets in the mainly hydrophilic environment. Phospholipase A_2 and carboxylesterase continue to break down fatty acids, cholesterol, monoglycerides, and other products of fat digestion. Proteolytic enzymes digest proteins into oligopeptides and free amino acids, while nucleases break down nucleic acids.[10,11]

The production of proteolytic enzymes in the pancreas occurs in a manner that prevents self-digestion of the pancreas. These enzymes are synthesized within the acinar cells and secreted into the duodenum as zymogens (inactive enzymes). Enterokinase secreted by the duodenal mucosa converts trypsinogen to trypsin, which then activates all other proteolytic zymogens along with procolipase and prophospholipase A_2. Thus two important mechanisms protect the pancreas from the potential degradative action of its own digestive enzymes. First, the synthesis of proteolytic enzymes as zymogens requires extrapancreatic activation by trypsin. Second, pancreatic juice contains a low concentration of trypsin inhibitor, which inactivates any autocatalytically formed trypsin within the pancreas. Proteolytic activity of trypsin in the intestinal lumen is not inhibited because the concentration of trypsin inhibitor is minimal. Lipase, amylase, ribonuclease, and deoxyribonuclease are secreted by the acinar cells in their active form.[10]

The regulation of exocrine pancreatic secretion is a complex interplay of neurohormonal feedback with three distinct phases. The first phase is the cephalic phase where the sight, smell, and taste of food produce pancreatic enzyme secretion through stimulus of the vagus nerve. Vasoactive intestinal peptide (VIP) and gastrin-releasing peptide (GRP) released from efferent vagus nerve terminals bind to receptors on the acinar cells stimulating enzyme release.[10] Water and bicarbonate are also released from ductal cells due to VIP stimulation. The gastric phase occurs due to gastric distension from food entering the stomach. This results primarily in secretion of digestive enzymes from the pancreas. Once chyme enters the duodenum the intestinal phase begins. The chyme causes secretin to be released from the duodenal mucosa when its pH is less than 4.5. Secretin results in water and bicarbonate secretion from the pancreas, which is necessary since lipolytic enzymes are inactivated at a pH below 5.[11] Digestive enzymes are released from the pancreas due to the presence of fatty acids, peptides, amino acids, and glucose in the duodenum.[10]

The feedback mechanism for continued release of pancreatic enzymes involves the hormone cholecystokinin (CCK). When products of fat, protein, and starch digestion enter the upper small intestine they stimulate release of CCK from I cells into the blood. Elevated levels of CCK in the serum activate a vagovagal reflex causing further release of VIP and GRP, leading to enhanced pancreatic enzyme secretion. Inhibition of this feedback loop is thought to be due to trypsin. After digestion is complete unoccupied trypsin is thought to inhibit the release of CCK.[10] A more in-depth discussion of pancreatic physiology can be found elsewhere.[10]

ACUTE PANCREATITIS

Acute pancreatitis varies from mild to severe disease. The morphological appearance of the pancreas and surrounding tissue ranges from interstitial edema and inflammatory cells (interstitial pancreatitis) to pancreatic and extrapancreatic necrosis (necrotizing pancreatitis). Necrotizing pancreatitis has a higher risk of infection, organ failure, and mortality.[2] The rupture of blood vessels within or around the pancreas can also lead to a collection of blood in the retroperitoneal space.

ETIOLOGY

Table 46–1 lists the etiologic risk factors associated with acute pancreatitis. Obstruction caused by gallstones is the most common

TABLE 46-1 Etiologic Risk Factors Associated with Acute Pancreatitis

Structural	Gallstone disease, sphincter of Oddi dysfunction, pancreas divisum, pancreatic tumors
Toxins	Alcohol (ethanol) consumption, scorpion bite, organophosphate insecticides
Infectious	Bacterial, viral (including AIDS), parasitic
Metabolic	Hypertriglyceridemia, chronic hypercalcemia
Genetic	Cystic fibrosis, α_1-antitrypsin deficiency, hereditary (trypsinogen gene mutations)
Medications	See Table 46–2 for specific drugs
Iatrogenic	Abdominal surgery, ERCP
Kidney disease	Chronic kidney disease, dialysis-related
Trauma	Blunt abdominal trauma
Vascular	Vasculitis, atherosclerosis, cholesterol emboli, coronary artery bypass surgery
Other etiologies	Congenital, Crohn disease, autoimmune, tropical, solid organ transplantation (e.g., liver, kidney, heart), refeeding syndrome
Idiopathic	Undetermined cause

AIDS, acquired immune deficiency syndrome; ERCP, endoscopic retrograde cholangiopancreatography.
Data from references 1, 2, 8, 13, 15.

TABLE 46-2 Medications Associated with Acute Pancreatitis

Class I (Definite Association)	Class II (Probable Association)	Class III (Possible Association)	
5-Aminosalicylic acid	Acetaminophen	Aldesleukin	Indomethacin
Asparaginase	Carbamazepine	Amiodarone	Infliximab
Azathioprine	Cisplatin	Calcium	Ketoprofen
Corticosteroids	Erythromycin	Celecoxib	Ketorolac
Cytarabine	Hydrochlorothiazide	Clozapine	Lipid emulsion
Didanosine	Interferon alpha-2b	Cholestyramine	Lisinopril
Enalapril	Lamivudine	Cimetidine	Mefenamic acid
Estrogens	Octreotide	Ciprofloxacin	Metformin
Furosemide	Sitagliptin	Clarithromycin	Methyldopa
Mercaptopurine		Clonidine	Metolazone
Opiates		Cyclosporine	Metronidazole
Pentamidine		Danazol	Nitrofurantoin
Pentavalent antimonials		Diazoxide	Omeprazole
Sulfasalazine		Etanercept	Ondansetron
Sulfamethoxazole and trimethoprim		Ethacrynic acid	Oxyphenbutazone
Sulindac		Exenatide	Paclitaxel
Tetracycline		Famciclovir	Pravastatin
Valproic acid/salts		Glyburide	Propofol
		Gold therapy	Propoxyphene
		Granisetron	Rifampin
		Ibuprofen	Sertraline
		Indinavir	Zalcitabine

Data from references 27, 125–127.

cause of acute pancreatitis and alcohol abuse the second; together they account for 70% to 80% of all cases of acute pancreatitis.[6] There has been an increase in identification of genetic and autoimmune causes of acute pancreatitis.[12] Most of the remaining cases are idiopathic.[9,13] Acute pancreatitis occurs in 1.8% to 7.2% of all patients who have undergone endoscopic retrograde cholangiopancreatography (ERCP), and in 30% to 40% of high-risk patients.[8,13,14] End-stage kidney disease increases the risk of acute pancreatitis, with patients who are receiving chronic peritoneal dialysis being at higher risk than those receiving hemodialysis.[15] Cigarette smoking appears to increase the risk of pancreatitis, especially in alcohol-related disease.[16] Pregnancy is not considered a cause of acute pancreatitis; however, pregnant women develop pancreatitis as a result of a coincident process, most commonly cholelithiasis. In pediatric patients, the common etiologies are systemic illness, biliary disease, trauma, and medications.[17]

Medications

Drug-induced acute pancreatitis should be suspected when other causes have been excluded and there is a temporal relationship with the initiation of a medication that has been implicated as a cause. The percentage of acute pancreatitis cases caused by medications is 0.1 to 2%.[18] Most information on drug-induced acute pancreatitis is obtained from case reports.[19–24] Proton pump inhibitors and histamine$_2$-receptor antagonists may be initiated in response to early symptoms of unrecognized pancreatitis and may confound the association between the drug and the disease. However, a retrospective cohort study does not support an association between acute pancreatitis and proton pump inhibitors or histamine$_2$-receptor antagonists.[19] Medications such as propofol and tamoxifen are associated with pancreatitis from hyperlipidemia.[22,24] There is a higher incidence of drug-induced acute pancreatitis in U.S. patients with human immunodeficiency virus (HIV) treated with antiretroviral therapy.[25] However, there was no increase in acute pancreatitis associated with antiretroviral use in a well-controlled trial including data from 33,742 person-years.[26] Medications used in the treatment of inflammatory bowel disease and type 2 diabetes mellitus have also been associated with a higher incidence of drug-induced acute pancreatitis.[18,27] Metformin is associated with acute pancreatitis at toxic serum concentrations.[23] The onset after initiation of these medications ranges from a few months to several years, with a median of 5 weeks; onset after rechallenge can occur within hours. The onset may differ according to the mechanism. Clinicians should be especially suspicious of drug-induced acute pancreatitis in high-risk patients, such as those receiving multiple medications or immunomodulating drugs, and in geriatric, HIV-positive, and cancer patients.[27]

Numerous drugs are believed to cause acute pancreatitis, but ethical and practical considerations prevent rechallenge with suspected agents.[28] Table 46–2 lists specific agents associated with acute pancreatitis based on known association. Class I (definite association) implies a temporal relationship of drug administration to abdominal pain and hyperamylasemia in at least 20 reported cases with at least one positive response to rechallenge with the offending agent. Class II medications are implicated in more than ten, but less than 20, reported cases of acute pancreatitis and suggest a probable association. Class III includes medications with a possible association, defined as fewer than 10 published cases or unpublished reports in pharmaceutical or U.S. Food and Drug Administration files. Table 46–2 includes only selected class III medications. A comprehensive list of class III drugs can be found elsewhere.[29]

Mechanisms of drug-induced pancreatitis are not clearly defined but may fall into several general categories, including direct toxic effects of the drug or its metabolites, hypersensitivity, drug-induced hypertriglyceridemia, and alterations of cellular function in the pancreas and pancreatic duct.[18] Once the process is initiated, disease severity is determined by the propagation of proinflammatory mediators. Although acute pancreatitis is an infrequent complication of drug therapy it is prudent to withdraw medication when an association is suspected.

PATHOPHYSIOLOGY

The pathophysiology of acute pancreatitis is based on events that initiate injury and secondary events that establish and perpetuate the injury (Fig. 46–2). Alcohol abuse and gallstones cause different

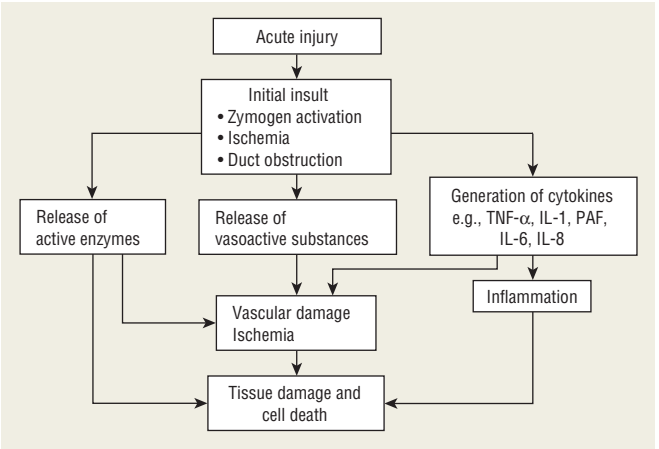

FIGURE 46-2. Pathophysiology of acute pancreatitis: initiating and secondary events. (IL-1β, interleukin-1β; IL-6, interleukin-6; IL-8, interleukin-8; PAF, platelet-activating factor; TNF-α, tumor necrosis factor-α.)

initial insults to the pancreas. However, acute pancreatitis of any etiology involves the premature activation of trypsinogen to trypsin within the pancreas, leading to activation of other digestive enzymes and autodigestion of the gland.[1,2] The lysosomal proteinase, cathepsin B, and intracellular calcium may be involved in the activation of trypsinogen as well as decreased activity of trypsin inhibitor.[30] Genetic abnormalities in pathways that protect the pancreas from autodigestion also play a pathophysiologic role in the development of some forms of acute pancreatitis, and may be the differentiating factor in the minority of alcoholics that develop disease.[1,31]

In addition to increased production, activated enzymes are retained in the acinar cells in higher concentrations than normal.[32] Activated pancreatic enzymes released into the pancreas and surrounding tissues produce damage and necrosis to the pancreatic tissue, the surrounding fat, the vascular endothelium, and adjacent structures. Lipase damages the fat cells, producing noxious substances that cause further pancreatic and peripancreatic injury. The release of cytokines by acinar cells directly causes their injury and enhances the inflammatory response.[30] Injured acinar cells liberate chemoattractants that recruit neutrophils, macrophages, and other cells to the area of inflammation. These immune responses cause a systemic inflammatory response syndrome (SIRS). Vascular damage and ischemia cause the release of kinins, which make capillary walls permeable and promote tissue edema. The release of damaging oxygen-free radicals appears to correlate with the severity of pancreatic injury.[2] Finally, pancreatic infection may result from increased intestinal permeability and translocation of colonic bacteria.[31,33]

COMPLICATIONS

Early complications are a result of fluid losses and SIRS. Hypotension results from hypovolemia, hypoalbuminemia, the release of kinins, and sepsis. Even patients with mild disease have significant fluid losses. Renal complications are usually caused by hypovolemia. Pulmonary complications develop when fluid accumulates within the pleural space compressing the lungs, and with development of the acute respiratory distress syndrome (ARDS), which limits gas exchange. The differential diagnosis for hypoxemia should include ARDS in patients with acute pancreatitis who do not have a history of pulmonary disease.[3] Pleural effusions occur in 4% to 17% of patients, more frequently on the left.[2] Gastrointestinal bleeding occurs secondary to numerous causes, including rupture of a pseudocyst (collection of pancreatic secretions and tissue debris enclosed by a wall of fibrous or granulation tissue). Severe acute pancreatitis is also associated with confusion and coma.

Local complications including acute fluid collection, pancreatic necrosis, infection, abscess (collection of pus in or adjacent to the pancreas), and pseudocyst develop approximately 3 to 4 weeks after the initial attack. Pancreatic infections occur in 15% to 30% of those with pancreatic necrosis and are usually secondary infections of necrotic tissue.[8] Pancreatic ascites occur when pancreatic secretions spread throughout the peritoneal cavity. Systemic complications include cardiovascular, renal, pulmonary, metabolic, hemorrhagic, and central nervous system abnormalities.[2] Long-term complications include glucose intolerance and recurrence of acute pancreatitis.[34]

CLINICAL PRESENTATION

Signs and Symptoms

The clinical presentation of acute pancreatitis varies depending on the severity of the inflammatory process and whether damage is confined to the pancreas or involves local and systemic complications (Table 46–3).[2,8,9]

Diagnosis

Most guidelines agree that the diagnosis should be made within 48 hours based on characteristic abdominal pain and amylase, lipase, or both being elevated to at least three times the upper limit of normal. Lipase is more sensitive and specific than amylase and is preferred. Contrast-enhanced computed tomography (CECT) of the abdomen may be used to confirm the diagnosis, including in patients with amylase or lipase levels that are not three times the upper limit of normal. Some guidelines consider ultrasonography to be an acceptable alternative to CECT.[2,35] However, it is best used to ascertain the presence of gallstones. The diagnosis of acute pancreatitis should also be considered when evaluating patients with SIRS (see Table 46–3).[1,2,35–37] For further information on laboratory tests and abdominal imaging refer to Table 46–3.

Prediction of Disease Severity Prediction of severity of acute pancreatitis is useful for decisions involving the need for aggressive treatment, including admission to intensive care units. The risk for severe acute pancreatitis should be assessed upon admission and on an ongoing basis.[2,3] Several recognized scoring systems have been developed to assess the likelihood of severe disease (Table 46–4). However, development and validation of such systems remains an ongoing area of research. The Ranson criteria scoring system was developed for pancreatitis and assesses 11 variables that must be monitored at the time of admission and during the initial 48 hours of hospitalization.[2,9] Severe acute pancreatitis is characterized by three or more criteria. Patients with fewer than three Ranson criteria have a mortality rate of less than 1%, whereas those with six or more have a 100% mortality rate.[2] The Ranson criteria are complete only after 48 hours. The Atlanta scoring system was developed based on consensus opinions; it consolidates clinical indicators, organ failure, and local complications to provide an ongoing assessment of disease severity.[8,9] The Acute Physiology and Chronic Health Evaluation II (APACHE II) system uses 12 indicators of physiologic and biochemical function, age, and previous health status to predict mortality in critically ill patients, but it is not specific to pancreatitis. The APACHE II score is calculated within the first 24 hours and is considered among the best predictors of severity on admission. A score greater than or equal to 8 points is considered the threshold for severe acute pancreatitis.[2,8,9] A modification, called the APACHE-O, improves predictive value in acute pancreatitis by adding points for a body mass index of 26 kg/m^2 or more.[38]

TABLE 46-3 Presentation and Diagnosis of Acute Pancreatitis

General
- The patient may have acute mild symptoms or present with a severe acute attack with life-threatening complications.

Symptoms
- The patient may present initially with moderate abdominal discomfort to excruciating pain, nausea, shock, and respiratory distress.
- Abdominal pain occurs in 95% of patients. The pain is usually epigastric and radiates to either of the upper quadrants or the back in two thirds of patients. In gallstone pancreatitis, the pain is typically sudden and quite severe, and the intensity is often described as "knife-like" or "boring." The pain usually reaches its maximum intensity within 30 minutes and may persist for hours or days. Repositioning the patient relieves very little of the pain. In alcohol abuse and other cases, the onset of pain may be less abrupt and poorly localized. Pain may not be the dominant symptom if it is masked by multiorgan failure.
- Nausea and vomiting occur in 85% of patients and usually follow the onset of abdominal pain. Vomiting does not provide relief of the abdominal pain.

Signs
- Marked epigastric or diffuse tenderness on palpation with rebound tenderness and guarding in severe cases. The abdomen is often distended and tympanic, with bowel sounds decreased or absent in severe disease.
- Vital signs may be normal, but hypotension, tachycardia, and low-grade fever are sometimes observed, especially with widespread pancreatic inflammation and necrosis.
- Dyspnea and tachypnea are often signs of acute respiratory complications. Jaundice and altered mental status may be present and have multiple causes. Other signs of alcoholic liver disease may be present in patients with alcoholic pancreatitis.

Laboratory tests
- Leukocytosis is frequently present; hyperglycemia or hypoalbuminemia may be present. Liver transaminases, alkaline phosphatase, and bilirubin are usually elevated in gallstone pancreatitis and in patients with intrinsic liver disease. Elevated serum triglycerides may also be a possible etiology.
- The hematocrit may be normal, but hemoconcentration results from multiple factors (e.g., vomiting). In patients with third-space fluid loss, hemoconcentration is present and a reasonably accurate marker of severe disease. A hemoglobin concentration of >47% predicts severe acute pancreatitis and one of <44% predicts mild disease. Further, failure to reverse hemoconcentration has been associated with pancreatic necrosis.
- The total serum calcium is usually normal initially, but hypocalcemia disproportionate to the hypoalbuminemia may develop. Marked hypocalcemia is an indication of severe necrosis and a poor prognostic sign.
- The serum amylase concentration usually rises within 4 to 8 hours of the initial attack, peaks at 24 hours, and returns to normal over the next 8 to 14 days. Serum amylase concentrations greater than three times the upper limit of normal are highly suggestive of acute pancreatitis. Persistent elevations suggest extensive pancreatic necrosis and related complications. Normal concentrations may be observed if testing is delayed (i.e., amylase may have returned to normal) or in patients with hyperlipidemic pancreatitis (i.e., marked triglyceride elevations may interfere with amylase assay). In addition, many nonpancreatic diseases may be associated with hyperamylasemia, including salivary, kidney, hepatobiliary, metabolic, female reproductive tract, and neoplastic diseases.[2,8]
- Serum lipase is specific to the pancreas, and concentrations are elevated and parallel the elevations in serum amylase. Levels remain elevated with pancreatic inflammation and return to normal when the inflammatory process resolves. Because of its longer half-life, elevations of serum lipase can be detected after the serum amylase has returned to normal.
- C-reactive protein (CRP) is a widely available test and levels greater than 150 mg/L at 48–72 hours predict severe acute pancreatitis with accuracy similar to that of APACHE II. Newer markers (e.g., urinary trypsinogen activation peptide) provide both diagnostic and prognostic information but are not routinely used in practice.
- Thrombocytopenia and an increase in the international normalized ratio are seen in some patients with severe acute pancreatitis and associated liver disease.

Abdominal imaging
- CECT is used to identify the cause of pancreatitis and confirm the diagnosis. It is less accurate for evaluating the gallbladder and biliary ducts. The test distinguishes interstitial from necrotizing pancreatitis but does not distinguish between fat necrosis and acute fluid collection. Tests that are performed in the first few days may miss necrosis. A CECT performed too early may result in unnecessary exposure to risk and increased cost. Formal scoring systems may be used to evaluate the findings.
- Magnetic resonance imaging is used to grade the severity of acute pancreatitis, to identify biliary duct problems that are not seen on CT, or if there are contraindications to CECT. Patients over the age of 40 with pancreatitis of an unknown etiology should be evaluated for pancreatic malignancy with CT or endoscopic ultrasonography.
- Ultrasonography of the abdomen is useful to determine pancreatic enlargement and peripancreatic fluid collections. It is also sensitive for detecting dilated biliary ducts and stones in the gallbladder.

APACHE, acute physiologic and chronic health evaluation; CECT, contrast-enhanced computed tomography; CT, computed tomography.
Data from references 8, 38, 45, 128.

Some studies have found obesity to be an independent risk factor for complications of acute pancreatitis.[38] Mortality from acute pancreatitis is strongly correlated with additional organ failure, especially persistent multisystem organ failure. Research continues for a sensitive scoring system that can be used early in the course of acute pancreatitis.[39]

CLINICAL COURSE AND PROGNOSIS

The clinical course of acute pancreatitis varies from a mild transitory disorder to a severe necrotizing disease. Mild acute pancreatitis is self-limiting and subsides spontaneously within 3 to 5 days. Mortality increases with unfavorable early prognostic signs, local complications, and organ failure. Pancreatic necrosis carries a 10% mortality, but this increases to 30% to 40% with infected necrosis.[2] Mortality is influenced by etiology, as idiopathic and postoperative acute pancreatitis have higher rates than gallstone- or alcoholically-induced disease. First and second occurrences also carry a higher mortality than subsequent episodes. Death during the first few days results from SIRS and multiorgan failure. When death occurs after this period, it is usually a result of infected necrosis, pancreatic abscess, and sepsis.[2]

TREATMENT

Acute Pancreatitis

DESIRED OUTCOME

Treatment of acute pancreatitis is aimed at relieving abdominal pain and nausea, replacing fluids, correcting electrolyte, glucose, and lipid abnormalities, minimizing systemic complications, and preventing pancreatic necrosis and infection. Management varies depending on the severity of the attack (Fig. 46–3). Patients with mild acute pancreatitis respond very well to the initiation of supportive care and the reduction of pancreatic secretions. Patients with severe acute pancreatitis should be treated aggressively and monitored closely.

TABLE 46-4 Prognostic Indicators for Severe Acute Pancreatitis

Prognostic Factor	Criterion
Ranson criteria	
On admission	
Age (y)	>55
WBC (cells/mm^3)	>16,000
Glucose (mg/dL)	>200
LDH (IU/L)	>350
AST (units/L)	>250
Within 48 hours	
Decrease in hematocrit (% points)	>10
Increase in BUN (mg/dL)	>5
Calcium (mg/dL)	<8
PaO_2 (mm Hg)	<60
Base deficit (mmol/L)	>4
Estimated fluid deficit (L)	>6
Atlanta criteria	
Unfavorable prognostic signs	
Ranson criteria	≥3
APACHE II score	≥8
Organ failure (shock)	
SBP (mm Hg)	<90
Pulmonary insufficiency (PaO_2 mm Hg)	<60
Kidney failure after hydration [serum creatinine (mg/dL)]	>2
Gastrointestinal tract bleeding (mL in 24 h)	>500
Systemic complications	
Disseminated intravascular coagulation	
Platelets (mm^3)	≤100,000
Fibrinogen (g/L)	<1
Fibrin-split products (m/mL)	>80
Metabolic disturbance	
Calcium (mg/dL)	≤7.5
Local complications	
Pseudocyst	Present
Necrosis	Present
Abscess	Present

Data from Topazian and Gorelick[56] and Whitcomb.[9]

GENERAL APPROACH TO TREATMENT

All patients with acute pancreatitis should receive supportive care, including intravenous fluid resuscitation, adequate nutrition, and effective relief of pain and nausea. The use of nasogastric aspiration offers no clear advantage in patients with mild acute pancreatitis, but it is beneficial in patients with profound pain, severe disease, paralytic ileus, and intractable vomiting.[2] Patients predicted to follow a severe course will require treatment of cardiovascular, respiratory, renal, and metabolic complications.[1] Aggressive fluid resuscitation is essential to correct intravascular volume depletion. However, specific recommendations cannot be made from the current literature, and this is a subject of ongoing research.[40] The prognosis of the patient often depends on the rapidity and adequacy of volume restoration, as large quantities of fluid are sequestered within the peritoneal and retroperitoneal spaces 1. Vasodilatation from the inflammatory response, vomiting, and nasogastric suction contributes to hypovolemia and fluid and electrolyte abnormalities. Intravenous colloids may be required to maintain intravascular volume and blood pressure because fluid losses are high in protein. Patients with pancreatitis and SIRS should be treated according to SIRS guidelines. Intravenous potassium, calcium, and magnesium are used to correct electrolyte deficiency states. Insulin is used to treat hyperglycemia. Local complications resolve as the inflammatory process subsides. However, patients with necrotizing pancreatitis may require antibiotics and surgical intervention.[2] Medications listed in Table 46–2 should be discontinued if possible 2.

NONPHARMACOLOGIC THERAPY

Nonpharmacologic therapy includes ERCP for removal of any underlying biliary tract stones, surgery, and nutritional support. Surgery is indicated in patients with pancreatic pseudocyst or abscess or to drain the pancreatic bed if hemorrhagic or necrotic material is present. The need for admission to an intensive care unit should also be addressed.

Nutrition and Probiotics

Nutritional support plays an important role in the management of patients with mild or severe disease as acute pancreatitis creates a catabolic state that promotes nutritional depletion. This can impair recovery, increase the risk of complications, and prolong hospitalization.[41,42] Patients with mild acute pancreatitis can begin oral feeding when bowel sounds have returned and pain has resolved.[8] In severe or complicated disease, nutritional deficits develop rapidly and are complicated by tissue necrosis, organ failure, and surgery. Nutritional support should begin when it is anticipated that oral nutrition will be withheld for more than 1 week.[43,44] In the past, there was concern that enteral feeding stimulated pancreatic enzyme secretion and exacerbated the underlying disease. However, numerous studies have shown that enteral feeding in severe acute pancreatitis is as safe and effective as parenteral nutrition, attenuates the acute inflammatory response, and improves disease severity.[41,43,44] The mechanisms for this include protection of the gut barrier and prevention of colonization with pathogenic bacteria, both of which may prevent translocation of bacteria and infection.[45] Therefore, the enteral route is preferred over the parenteral in patients with severe acute pancreatitis, provided that it can be tolerated. More specifically, the nasojejunal route may be preferred,[2] but the nasogastric route also appears to be safe and effective.[37,42,46] If enteral feeding is not possible or if the patient is unable to obtain sufficient nutrients, parenteral nutrition should be implemented before protein and calorie depletion become advanced. Intravenous lipids should not be withheld unless the serum triglyceride concentration is greater than 500 mg/dL.[2] Preliminary data suggest that the early nasojejunal administration of probiotics, such as lactobacillus, with enteral nutrition may reduce bacterial translocation and possibly decrease pancreatic necrosis and abscess.[47,48]

PHARMACOLOGIC THERAPY

Recommendations

Besides fluid resuscitation and nutritional support patients with acute pancreatitis require treatment for pain and nausea. Pain and nausea can be treated with intravenous analgesics and antiemetics. Antisecretory agents may be used to prevent stress-related mucosal bleeding. Octreotide may be tried in severe acute pancreatitis, but its efficacy remains uncertain (see Fig. 46–3). The use of prophylactic antibiotics is controversial and most guidelines do not support this practice.[2,37]

Relief of Abdominal Pain

Parenteral opioid analgesics are used to control abdominal pain associated with acute pancreatitis 3. The most important factors to consider in selecting an analgesic are efficacy and safety. Although the administration of some opioids is associated with mild and transient increases in serum amylase and lipase, these effects

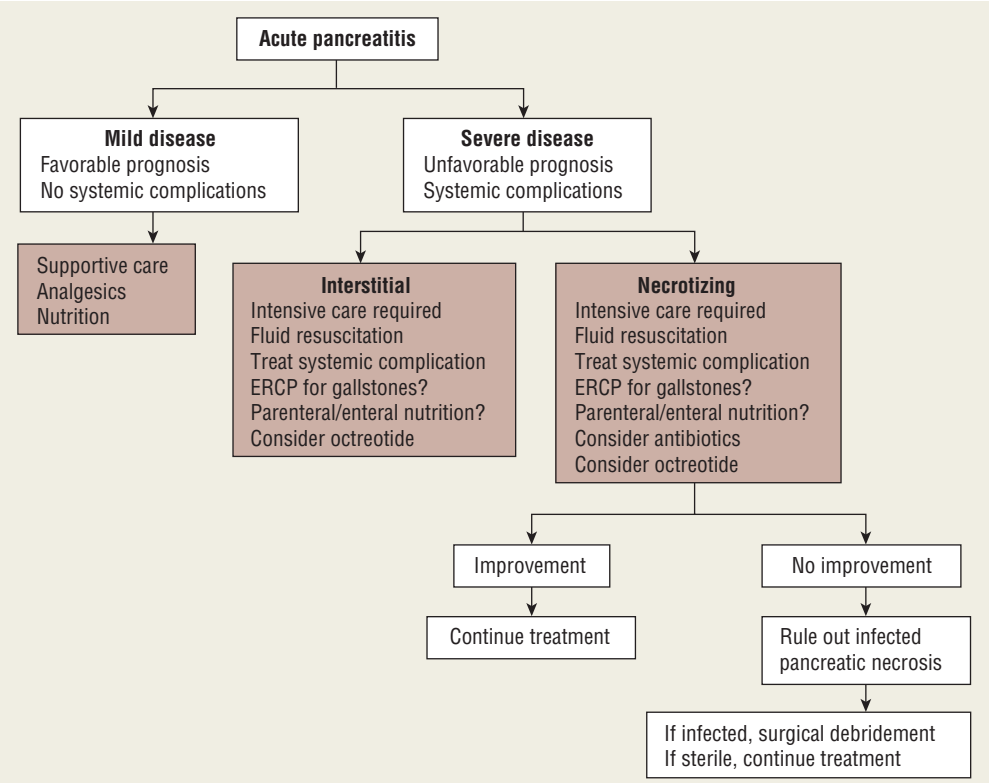

FIGURE 46-3. Algorithm of guidelines for evaluation and treatment of acute pancreatitis. (ERCP, endoscopic retrograde cholangiopancreatography.)

are not deleterious to the patient. Traditionally, treatment was initiated with parenteral meperidine (50 to 100 mg every 3 to 4 hours) because it did not significantly alter the function of the sphincter of Oddi (see Fig. 46–1), thereby worsening the disease course.[49,50] However, meperidine is not recommended as a first-line agent because of the risk of adverse effects and dosing limitations 4. As a result many hospitals have either restricted or eliminated the use of meperidine. Active metabolites of meperidine accumulate with kidney dysfunction and may cause seizures or psychosis. The maximum recommended parenteral dose of meperidine is 600 mg/day in divided doses in patients with normal kidney function, but it should not be used in patients with kidney dysfunction.

Parenteral morphine is often recommended for pain control because it provides a longer duration of pain relief than meperidine with less risk of seizures. However, its use in acute pancreatitis is sometimes avoided because it is thought to cause spasm of the sphincter of Oddi, increases in serum amylase, and, rarely, pancreatitis.[2] Although morphine increases biliary pressure, there is no evidence to indicate that it is contraindicated for use in acute pancreatitis as no studies have compared clinical outcomes of acute pancreatitis using various analgesics.[50] Hydromorphone may be used because it also has a longer half-life than meperidine. Patient-controlled analgesia should be considered in patients who require frequent opioid dosing (e.g., every 2 to 3 hours). Dosing of pain medications should be monitored carefully and adjusted daily. There is no evidence that antisecretory agents, such as histamine$_2$-receptor antagonists or proton pump inhibitors, prevent an exacerbation of abdominal pain.[51]

Limitation of Systemic Complications and Prevention of Pancreatic Necrosis

A number of agents have been investigated to limit disease progression by either directly or indirectly reducing pancreatic secretion, inhibiting the action of circulating inflammatory mediators, or increasing pancreatic microcirculation.[52–54] The use of parenteral histamine$_2$-receptor antagonists or proton pump inhibitors does not improve the overall outcome of patients with acute pancreatitis.[8] Similarly, corticosteroids are not useful in limiting systemic complications and altering the course of the disease.[52] Clinical studies with protease inhibitors such as aprotinin and gabexate have failed to show a mortality reduction in acute pancreatitis, and their use is not supported by guidelines.[2,8,35,37,52,53] Neither agent is currently available in the United States. Conflicting or inconclusive data exist regarding the efficacy of atropine, lexipafant, low-molecular-weight dextran, antioxidants such as N-acetylcysteine, indomethacin, interleukin-10, and infliximab.[52,54]

Somatostatin and its synthetic analog octreotide are potent inhibitors of pancreatic enzyme secretion and have been used to interrupt the inflammatory process. Several studies and a meta-analysis that evaluated the efficacy of somatostatin and octreotide suggest a slight trend toward benefit in patients with severe pancreatitis.[2,55] Limitations of these studies include small numbers of patients, no placebo, and inclusion of patients with mild disease.[53] There are insufficient data to support the routine use of somatostatin or octreotide in the treatment of acute pancreatitis, and guidelines do not recommend their use.[37]

Prevention of Infection

Prophylactic antibiotics do not offer any benefit in cases of mild acute pancreatitis or when there is no necrosis. Use of antibiotics in patients with severe acute pancreatic necrosis, but without infection, is not currently supported by randomized, controlled trials 5. This is true with or without the presence of pancreatic necrosis.

Antibiotic prophylaxis in early clinical trials showed no benefit, but these studies were limited due to inclusion of patients with a wide range of disease severity and insufficient enrollment of patients with severe necrotizing pancreatitis.[1,52] In addition, they used ampicillin, which does not penetrate well into pancreatic tissue.[52] Imipenem-cilastatin, metronidazole, cefotaxime, piperacillin,

TABLE 46-5 Clinical Trials of Intravenous Antibiotic Prophylaxis in Patients with Severe Acute Pancreatitis

Primary Author	Patients (*n*)	Cause of Acute Pancreatitis	Antibiotic Therapy

Dellinger et al.[63]	100	Any	Meropenem

mezlocillin, ofloxacin, and ciprofloxacin all achieve satisfactory bactericidal tissue concentrations, whereas aminoglycosides have poor penetration.[52,53,56] However, the importance of antibiotic penetration into pancreatic tissue has been debated, as it is the peripancreatic retroperitoneal necrotic fat and debris, not the pancreas itself, that becomes infected.

Several randomized clinical trials have compared antibiotic prophylaxis with no prophylaxis in patients with acute necrotizing pancreatitis with varying results (Table 46–5).[57–64] In one study, prophylaxis with cefuroxime lowered mortality, length of hospital stay, and the overall infection rate.[58] However, the decrease in total infections was attributed to fewer urinary tract infections in the antibiotic group. In contrast, other antibiotic regimens decreased the incidence of infections but had no effect on mortality.[57,59,60,63,64] The carbapenem agent imipenem-cilastatin has been used in two trials. A single-blind trial with 58 patients found a reduction in the need for surgery but no effect on mortality or sepsis.[61] An unblinded trial with 73 patients found a lower rate of infections but no difference in the need for surgery or mortality.[64] In contrast, a double-blind trial with 100 patients found no benefit from early antibiotic therapy using another carbapenem agent, meropenem.[63] Studies that included severe acute pancreatitis without computed tomography (CT) demonstration of necrosis failed to show a beneficial effect on mortality.[59,62] The two largest trials, which were also double-blind, did not demonstrate any benefit with prophylaxis.[62,63] Two meta-analyses and a Cochrane review concluded that prophylaxis with broad-spectrum antibiotics decreases sepsis and mortality in patients with severe acute pancreatitis and necrosis.[65–67] However, these were conducted prior to publication of two trials demonstrating no benefit.[63,64] A meta-analysis that included these two trials found prophylactic antibiotics do not reduce infected necrosis or mortality.[68] In addition, overuse of antibiotics increases microbial resistance. Currently, use of antibiotics in necrotizing pancreatitis is not recommended in the absence of infection.

Because the source of bacterial contamination in acute pancreatitis is most likely the colon, the choice of antibiotic should be broad spectrum, covering the range of enteric aerobic gram-negative bacilli and anaerobic microorganisms. Treatment should be initiated within the first 48 hours and continued for 2 to 3 weeks. Imipenem-cilastatin (500 mg every 8 hours) has been widely used because of its good penetration into the pancreas and one positive prophylaxis study.[64] However, it has been replaced on many hospital formularies by one of the newer carbapenems. Fluoroquinolones, such as ciprofloxacin or levofloxacin, combined with metronidazole should be considered for penicillin-allergic patients.[1,52]

Selective digestive tract decontamination uses oral nonabsorbable antibiotics to eradicate intestinal flora thereby reducing translocation.[56,69] This alternative may be of benefit in reducing the risk of pancreatic infection, but randomized, controlled trials in patients with acute pancreatitis are needed to confirm its effectiveness when compared with parenteral antibiotic prophylaxis.[1,2,52,56]

The use of prophylactic antibiotics is associated with an increase in the incidence of fungal and β-lactam-resistant gram-positive organisms.[70,71] The rise in fungal infections has led some clinicians to consider the addition of an antifungal agent to the prophylactic regimen.[72] Although agents such as fluconazole penetrate pancreatic tissue,[73] the effectiveness of prophylactic antifungal agents remains unproven, and there are no definitive recommendations for their use. Once infection develops in the patient with necrotic acute pancreatitis, surgical debridement is required.

CLINICAL CONTROVERSY

Some clinicians believe that antibiotic prophylaxis is necessary in patients with severe acute pancreatitis in order to prevent pancreatic infection, whereas others believe that this practice is unnecessary. Antibiotic use in acute pancreatitis remains controversial, especially in patients without definite proof of pancreatic necrosis.

POST-ERCP PANCREATITIS

The clinical characteristics of post-ERCP pancreatitis are similar to those of acute pancreatitis from other causes. In most cases the disease course is mild and resolves in several days. Pretreatment with octreotide, corticosteroids, calcium channel blockers, allopurinol, natural β-carotene, and aprotinin has been disappointing.[1,74,75] However, some benefit has been demonstrated with somatostatin, diclofenac suppositories, and gabexate.[1,76,77] To date, there have not been any studies to evaluate the cost-effectiveness of prophylactic therapy.[14,78,79]

CHRONIC PANCREATITIS

Chronic pancreatitis results from long-standing pancreatic inflammation resulting in irreversible destruction of pancreatic tissue with fibrin deposition, leading to a loss of exocrine and endocrine function.[4–6] It has four different stages, beginning with a preclinical inflammatory stage in which patients remain asymptomatic or have indistinguishable symptoms.[6] In the second stage patients present with acute attacks that often resemble those of acute pancreatitis. The third stage consists of episodes of intermittent or constant abdominal pain. Finally, in the burnout stage patients present with diminished or absent pain but develop malabsorption syndrome due to loss of pancreatic exocrine function and diabetes mellitus from loss of endocrine function.

ETIOLOGY

Chronic alcohol consumption, especially heavy drinking, remains the leading cause of chronic pancreatitis in Western society, accounting for approximately 70% to 80% of cases.[6,80] Generally, consumption of 100 to 150 g/day of alcohol over 10 to 15 years poses a significant risk of chronic pancreatitis.[81] Twenty percent of the remaining cases can be classified as idiopathic, while 10% are due to rare causes, such as autoimmune, hereditary, and tropical pancreatitis.[6,81] Various genetic alterations have also been associated with the occurrence of chronic pancreatitis, including mutations of the

TABLE 46-6 M-ANNHEIM Classification of Risk Factors for Chronic Pancreatitis

Pancreatitis with **M**ultiple risk factors	
Alcohol	Excessive consumption (>80 g/day)
	Increased consumption (20–80 g/day)
	Moderate consumption (<20 g/day)
Nicotine	Quantitated in pack-years for current smokers
Nutritional factors	High fat and protein diet
	Hyperlipidemia (esp. hypertriglyceridemia)
Hereditary factors	Hereditary pancreatitis
	Familial pancreatitis
	Early- and late-onset idiopathic pancreatitis
	Tropical pancreatitis
	Possible gene mutations (e.g., *PRSS1*, *SPINK1*, and *CFTR*)

cationic trypsinogen (*PRSS1*), serine protease inhibitor Kazal type 1 (*SPINK1*), and the cystic fibrosis transmembrane conductance regulator (*CFTR*) genes.[81–84] There is also a demonstrated risk of chronic pancreatitis with cigarette smoking that appears to be dose dependent and may contribute to mortality from chronic pancreatitis.[80,85–88] A proposed classification system called the M-ANNHEIM classification takes into account the various risk factors for chronic pancreatitis (Table 46–6).[89]

PATHOPHYSIOLOGY

Although the exact mechanism for the pathogenesis of chronic pancreatitis is unknown several theories have been proposed. The oxidative stress theory proposes that the pancreas is exposed to by-products of mixed-function oxidases that lead to an inflammatory reaction.[81,90] Increased activity of hepatic and pancreatic oxidases may be due to increased exposure to substrates (e.g., fat), inducers (e.g., alcohol), or other substances. A comparison of serum oxidative markers in chronic pancreatitis patients versus healthy volunteers supports this theory.[91] A toxic-metabolic theory focuses on alcohol as a primary causative agent where by-products of its metabolism in the pancreas lead to lipid accumulation in acinar cells and eventual fatty degeneration of the pancreas.[90] Ductal obstruction theories state that alcohol leads to obstruction of pancreatic ductals secondary to increased protein deposition and stone formation. This leads to scarring of ductal epithelial cells, which potentiates further obstruction and eventually results in acinar atrophy and fibrin deposition. The final major theory suggests that periductular necrosis from repeated episodes of acute pancreatitis eventually leads to ductal obstruction and stone formation with subsequent acinar atrophy and fibrosis.

Regardless of the pathophysiologic mechanism several pieces of evidence now point to activation of pancreatic stellate cells as the cause of fibrin deposition in chronic pancreatitis. Various toxins, oxidative stress, and inflammatory mediators have been shown to activate pancreatic stellate cells.[90,92] Cellular signaling pathways involved in this activation are modulated by hydroxymethylglutaryl-coenzyme A reductases and peroxisome proliferator-activated receptor-gamma nuclear receptors.[93] As an example, exposure of the pancreas to alcohol and its metabolites leads to the production of various mediators and proinflammatory cytokines, especially tumor necrosis factor alpha and interleukins 1 and 6.[92,93] These then activate pancreatic stellate cells, which initiate fibrinogenesis. Other mediators generated by the stellate cells themselves perpetuate continued stellate cell activation.

The pathogenesis of pain in chronic pancreatitis has long been thought to be the result of increased pancreatic parenchymal pressure from obstruction, inflammation, and necrosis.[94,95] A neurogenic mechanism may also be responsible. Continued activation of trypsin not only damages afferent neurons but also has effects on sensory pain receptors within the pancreas.[94] Changes also occur within the central nervous system that further contribute to the neurogenic mechanism of pain.[94,96,97] Therefore, compression of pancreatic nerve fibers after a meal along with continuous firing of peripheral and central neurons may explain the burning and shooting pain of chronic pancreatitis.[96]

CLINICAL PRESENTATION

Chronic pain, malabsorption with resultant steatorrhea, and diabetes mellitus are the hallmark complications and symptoms of chronic pancreatitis 6. Although abdominal pain is the most common symptom at any stage, patients may present with various signs and symptoms depending on the stage of the disease. A more comprehensive list of the common signs and symptoms is presented in Table 46–7.

Diagnosis

The diagnosis of chronic pancreatitis is based primarily on presenting signs and symptoms in combination with either imaging or pancreatic function studies (see Table 46–7). Although histology would be the best diagnostic test it is difficult and risky to perform and is generally not recommended.[82] Therefore, testing usually begins with noninvasive and inexpensive studies such as serum trypsinogen, fecal elastase, mixed triglyceride breath test, and abdominal ultrasonography.[4,98,99] However, these tests are usually useful only in advanced disease.[4] Magnetic resonance cholangiopancreatography or CT may be used next. The most sensitive studies are the secretin and CCK stimulation tests for exocrine pancreatic insufficiency.[5,81,82] Performing these studies is uncomfortable for patients and they are not widely available, so they are usually reserved to rule out chronic pancreatitis if imaging studies are nondiagnostic.[4,5] The gold standard invasive study is ERCP.[5,81] However, due to the risks associated with this procedure endoscopic ultrasonography (EUS) has become an accepted alternative for the diagnosis of chronic pancreatitis.[5,81,82,100]

Clinical Course and Prognosis

The clinical course of chronic pancreatitis depends upon the etiology. The median age at onset is as early as 10 years for hereditary chronic pancreatitis, whereas alcoholic and late-onset idiopathic chronic pancreatitis have median onsets of 36 and 62 years, respectively.[101] Exocrine insufficiency, which occurs when lipase secretion is less than 10% of normal,[4,81] develops about 5 years after diagnosis in alcoholic chronic pancreatitis and 22 years in hereditary chronic pancreatitis. Diabetes mellitus was shown to occur about 8 years after diagnosis of alcoholic chronic pancreatitis and up to 27 years after diagnosis of early-onset idiopathic chronic

TABLE 46-7 Signs, Symptoms, and Diagnosis of Chronic Pancreatitis

Signs
- Malnutrition (especially in chronic alcoholism)
- Abdominal mass (may indicate a pancreatic pseudocyst)
- Jaundice may be seen
- Splenomegaly (rare)

Symptoms
- Abdominal pain
  - Commonly in epigastric area
  - May radiate to the back
  - Described as deep and penetrating
  - May be relieved by bending/leaning forward or bringing knees to the chest
  - Often occurs with meals and at night
  - May be associated with nausea and vomiting
- Steatorrhea
  - Patients describe bulky or foul-smelling stools often with obvious oil droplets
  - Usually have an average of three to four stools per day
  - May be associated with deficiencies in fat-soluble vitamins
  - Watery diarrhea, excess gas, and abdominal cramps are uncommon
- Pancreatic diabetes mellitus
- Diarrhea (associated with steatorrhea)
- Weight loss
  - May be due to severe malabsorption or acute/chronic pain
  - Substantial loss may be due to associated or unrelated malignancy
- Dyspepsia

Laboratory studies
- CBC to rule out infection (i.e., infected pseudocyst)
- Serum amylase and lipase
  - Low specificity for chronic pancreatitis
  - May be elevated in acute exacerbations
  - Usually are normal or only slightly elevated
- Total bilirubin, alkaline phosphatase, and hepatic transaminases may be elevated with ductal obstruction
- Fasting serum glucose
- Pancreatic function tests
  - Serum trypsinogen (<20 ng/mL is abnormal)
  - Fecal elastase (<200 mcg/g of stool is abnormal)
  - Fecal fat estimation (>7 g/day is abnormal; need to collect 72 hours of stool)
  - Secretin stimulation (evaluates duodenal bicarbonate secretion)
  - ^{13}C-mixed triglyceride breath test
- Serum albumin (may be low with malnutrition)
- Serum calcium (may be low with malnutrition)

Imaging studies
- Noninvasive
  - Abdominal ultrasound
  - Computed tomography (CT)
  - Magnetic resonance cholangiopancreatography (MRCP)
- Invasive
  - Endoscopic ultrasonography (EUS)
  - Endoscopic retrograde cholangiopancreatography (ERCP)

CBC, complete blood count.
Data from references 4, 5, 129.

pancreatitis. Resolution of pain from pancreatic burnout tended to coincide with exocrine insufficiency.

The life expectancy of patients with chronic pancreatitis is shorter than that of the general population. The 10-year survival is 70%, while the 20-year rate was 45%.[6] However, death in patients with chronic pancreatitis most commonly results from cardiovascular disease, infection, or malignancy rather than from the disease itself.[6,101] One of the most significant complications of long-standing disease is pancreatic cancer. Patients with alcoholic chronic pancreatitis are 15 times as likely as the general population to develop pancreatic cancer, while 40% of those with hereditary chronic pancreatitis may be diagnosed.[6,81]

TREATMENT

Chronic Pancreatitis

DESIRED OUTCOME

The major goals in the treatment of uncomplicated chronic pancreatitis are relief of abdominal pain, treatment of the associated complications of malabsorption and diabetes mellitus, and improvement in quality of life. Secondary goals include treating associated disorders such as depression and malnutrition.

GENERAL APPROACH TO TREATMENT

Treatment of chronic pancreatitis and its complications involves various nonpharmacologic and pharmacologic interventions. Lifestyle modifications should include abstinence from alcohol and smoking cessation.[5,81] Also, patients with steatorrhea may need to eat smaller, more frequent meals and reduce dietary fat intake.[4,5] The majority of patients require analgesics and pancreatic enzyme supplementation.[5,81,82] Pain can initially be controlled with medications but may require more aggressive medical and surgical therapies as the disease progresses. Patients with malabsorption require pancreatic enzymes to reduce steatorrhea and maintain adequate nutrient absorption.[5,81] An antisecretory agent may be added to the regimen when enzymes alone provide an inadequate reduction in steatorrhea.[4,5,81]

NONPHARMACOLOGIC THERAPY

In addition to medical management the treatment of chronic pancreatitis includes both lifestyle and dietary modifications. Patients should be counseled to abstain from alcohol use, and smoking cessation should be advocated. It is unclear if cessation of alcohol use reduces pain in patients with alcoholic chronic pancreatitis, but its use hastens disease progression.[4] Patients with steatorrhea should be counseled to eat small and frequent meals.[102] A reduction in dietary fat is not needed empirically, but a decrease to 0.5 g/kg/day is recommended for those whose symptoms are uncontrolled with enzyme supplementation. Patients who do not consume adequate calories from their normal diet may be given whole protein or peptide-based oral nutritional supplements. Supplementation with medium-chain triglycerides, which do not require lipolysis, should be considered for patients with steatorrhea who are unable to gain weight. Complete enteral nutrition is recommended for patients who cannot consume adequate calories, have continued weight loss, experience complications, or require surgery. A jejunal feeding tube is the recommended route for administration of enteral nutrition in chronic pancreatitis patients; it increases patient weight and decreases abdominal pain and opioid use.[103]

Invasive procedures and surgery are primarily used to treat uncontrolled pain and the associated complications of chronic pancreatitis. Stents placed via ERCP may be used to treat pancreatic duct strictures in order to relieve parenchymal pressure and reduce pain.[95,100,104] Extracorporeal shock wave lithotripsy can be used to break up pancreatic stones with ultrasonic vibration prior to removal by ERCP.[95,100,104,105] However, combining these procedures to treat pain provides no additional benefit and increases cost.[106] Blockade of pain signals through the celiac plexus may be achieved utilizing EUS.[82,95,100,104] Some complications of chronic pancreatitis that can be treated endoscopically include common bile duct strictures, duodenal obstructions, and pancreatic pseudocysts.[100,104] Various surgical techniques, including total pancreatectomy, may also be used to relieve pain associated with chronic pancreatitis.[5,95,107] Surgery is more effective at relieving pain compared with endoscopic procedures, but these trials have a number of limitations.[108,109]

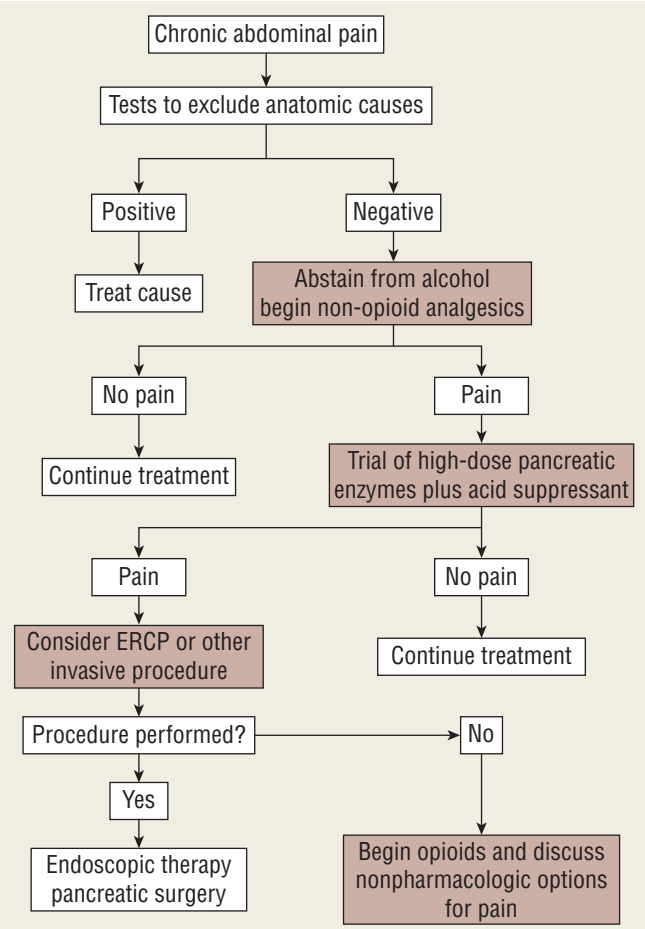

FIGURE 46-4. Algorithm for the treatment of abdominal pain in chronic pancreatitis. (ERCP, endoscopic retrograde cholangiopancreatography.)

Finally, total pancreatectomy with transplantation of pancreatic islet cells to reduce the need for exogenous insulin is a possible option for the treatment of pain due to chronic pancreatitis.[82,110]

PHARMACOLOGIC THERAPY

General Recommendations

Pharmacologic therapy of chronic pancreatitis is aimed at controlling pain, treating malabsorption and associated steatorrhea, and controlling diabetes mellitus. Once other causes have been excluded nonopioid analgesics should be tried initially for pain management (Fig. 46–4).[4,5] Patients unresponsive to nonopioid analgesics may be given a trial of pancreatic enzyme supplements prior to addition of opioids.[4,82,95] If these measures fail, an oral opioid should be added to the drug regimen. Opioids administered by nonoral routes should be reserved for patients who cannot take oral medications or whose pain is unresponsive to oral opioids. Additional agents may be considered for added pain control and disorders associated with chronic pancreatitis.

Most patients with malabsorption will require a modification in diet along with pancreatic enzyme supplementation in order to achieve adequate nutritional status and reduction in steatorrhea (Fig. 46–5). An antisecretory agent should be added to the regimen when there is an inadequate response to enzyme therapy alone.[4] If these measures are ineffective, documentation of the diagnosis and exclusion of other diseases should be undertaken. Exogenous insulin is the primary pharmacologic agent used in the treatment of diabetes mellitus associated with chronic pancreatitis.[4] However, some patients may have favorable results with the use of oral agents for control of blood glucose.

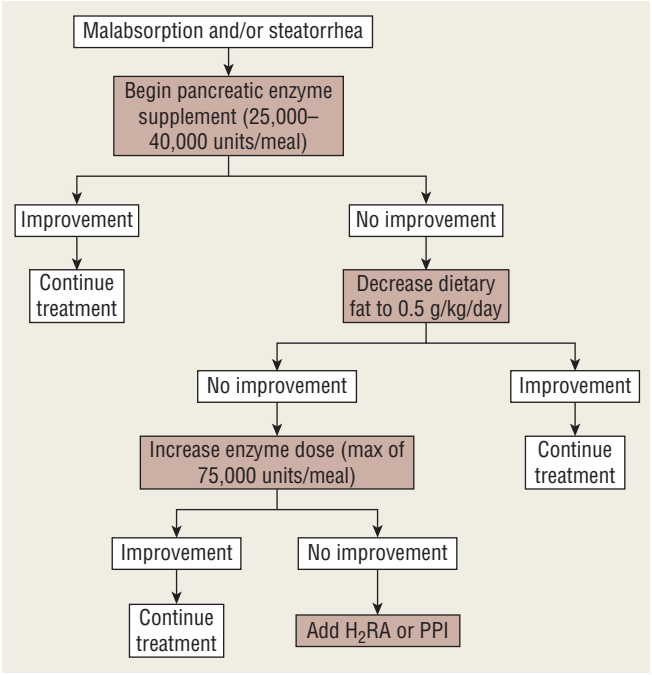

FIGURE 46-5. Algorithm for the treatment of malabsorption and steatorrhea in chronic pancreatitis. (H_2RA, hitamine$_2$-receptor antagonist; PPI, proton pump inhibitor.)

Relief of Chronic Abdominal Pain

Analgesics Pain from chronic pancreatitis can initially be treated with nonopioid analgesics, but opioids will eventually be required as the disease progresses 7. Therapy should begin with acetaminophen or nonsteroidal antiinflammatory drugs (NSAIDs) (Table 46–8).[4,5] Regimens should be individualized and should begin with the lowest effective dose. The dosage regimen should be maximized before adding or substituting agents. Analgesics should be scheduled around the clock rather than as needed in order to maximize efficacy. Also, scheduling analgesics prior to meals should help decrease postprandial pain. When nonopioid analgesics fail to control pain low-potency opioids (e.g., hydrocodone) should be added to the regimen (see Table 46–8). Tramadol has also been used successfully to treat pain in patients with chronic pancreatitis, but at a higher dose than that approved in the United States.[4] Severe pain unresponsive to these therapies necessitates the use of opiate analgesics. Although opioids carry about a 10% to 30% risk of addiction in this population their use should not be withheld.[4] Unless contraindicated, oral opioids should be used before parenteral, transdermal, or other dosage forms. Although oxycodone was found to relieve pain better than morphine in a study of simulated chronic pancreatitis pain, adequate trials comparing agents have not been conducted.[111] Therefore, the choice of agent should be based on cost, compliance, and avoidance of adverse drug events (e.g., allergic reactions).

CLINICAL CONTROVERSY

Since the evidence supporting the use of pancreatic enzyme supplements for treating pain associated with chronic pancreatitis is not overwhelming, clinicians debate over their use for this purpose. Often the decision to use enzyme supplements for the treatment of pain comes from clinical experience and the knowledge that their use carries minimal risk of adverse effects.

TABLE 46-8 Recommendations for the Pharmacologic Treatment of Chronic Pancreatitis

Treatment of chronic pain (oral drug regimens)

Nonopioids

- Acetaminophen: Dosage should be limited to 500 mg four times a day if patient drinks more than two alcoholic beverages per day; increased risk of hepatotoxicity, especially in chronic alcohol use
- Nonsteroidal antiinflammatory drugs (NSAIDs): Standard dosage regimens of aspirin or traditional NSAIDs (e.g., ibuprofen). Use with caution in patients at risk for upper GI bleeding and with kidney dysfunction
- Tramadol: 50–100 mg every 4–6 hours, not to exceed 400 mg/day; has opioid-like effect; contraindicated in alcohol or hypnotic intoxication; be aware of drug interactions; expensive
- Consider use of selective serotonin reuptake inhibitors (e.g., paroxetine) or tricyclic antidepressants in difficult-to-manage patients

Opioids

- Codeine 30–60 mg every 6 hours; hydrocodone 5–10 mg every 4–6 hours; morphine sulfate (extended-release) 30–60 mg every 8–12 hours; oxycodone 5–10 mg every 6 hours; methadone 2.5–10 mg every 8–12 hours; hydromorphone 0.5–1 mg every 4–6 hours; fentanyl patch 25–100 mcg/h every 72 hours
- Risk of potentiation with alcohol; impaired respiration; constipation; hypotension; allergy
- Dosing is usually based on providing continuous pain relief; consider combining with acetaminophen or NSAIDs; opioid dependence is common; abuse is a concern in alcoholics; tolerance may develop

Pancreatic enzymes

- Four to eight tablets of a preferred product (see Table 46–9) with each meal plus either a histamine$_2$-receptor antagonist or proton pump inhibitor; no clinical trials support such a regimen for pain management

Treatment of malabsorption and steatorrhea

- Start with 25,000–40,000 USP units of lipase with each meal of a preferred product (see Table 46–9); administer dose during or just after meals
- Increase dose to a maximum of 75,000 USP units per meal
- Products containing enteric-coated microspheres or minimicrospheres may be more effective than other dose forms

Acid suppression agents

- May improve efficacy of enzyme therapy for malabsorption and steatorrhea
- May allow a lower dose of enzyme supplements to be used

Pancreatic Enzymes Although pancreatic enzymes are primarily used to treat malabsorption associated with chronic pancreatitis they are also used to treat pain from the disease. Relief of pain using pancreatic enzymes is thought to be due to their ability to break down CCK.[4,11,82,95] Normally, the release of CCK, which causes an increase in pancreatic secretion, is inhibited by trypsin. However, there is a decrease in the production of trypsin in patients with chronic pancreatitis. This leads to a loss of negative feedback on the release of CCK and thus an increase in pain due to unabated pancreatic secretion. The proteases in pancreatic enzyme supplements are thought to act as substitutes for endogenous trypsin, leading to a decrease in CCK release.

Despite this intuitive mechanism there were mixed results from trials investigating pancreatic enzyme supplements for the treatment of pain from chronic pancreatitis. This may be due to the differences between the various enzyme formulations used in the trials as well as the small number of subjects enrolled.[4,11,82,95] A meta-analysis that pooled the results of all six prospective trials found no benefit with the use of enzyme supplements for pain relief.[112] However, the two trials that used non-enteric-coated enzyme formulations demonstrated a benefit in the treatment of pain.[4,11,82,95] Enteric-coated formulations may not release enough proteases in the duodenum to inhibit CCK release. However, non-enteric-coated products are no longer available in the United States. Therefore, it may be reasonable to administer an enteric-coated product with an antisecretory agent in order to increase the amount of proteases available in the duodenum (see Table 46–8). No studies have been conducted using such a regimen for the treatment of pain from chronic pancreatitis.

Other Agents Various adjunctive agents are also used in patients experiencing pain from chronic pancreatitis. Selective serotonin reuptake inhibitors and tricyclic antidepressants are used both for treating the concomitant depression that often occurs in patients with chronic pancreatitis and for their potential effects on pain (see Table 46–8).[4,95] Gabapentin has also been used as an adjunct to opioids.[4] Little evidence supports these therapies, but their use in this patient population is not uncommon. Octreotide and allopurinol have also been studied for the treatment of chronic pancreatitis pain, but the evidence does not support their use.[4,95] There is evidence showing that patients with chronic pancreatitis have increased oxidative stress, and the use of antioxidants, such as selenium, vitamins C and E, and beta-carotene, has demonstrated some benefit in relieving pain and improving quality of life in these patients.[113–116]

Treatment of Malabsorption

Pancreatic enzyme supplementation and reduction in dietary fat intake are the primary treatments for malabsorption due to chronic pancreatitis 8. Treatment should begin when steatorrhea is documented and persistent weight loss occurs despite initial dietary modifications. The combination of pancreatic enzymes and a reduction in dietary fat enhances the patient's nutritional status and reduces steatorrhea. Malabsorption is minimized if the concentration of lipase delivered to the duodenum with supplementation is about 10% of normal pancreatic output.[4] This requires that 25,000 to 40,000 units of lipase be administered with each meal (see Table 46–8).[11] In many cases the lipase dose will need to be increased due to insufficient lipolytic activity, but doses greater than 75,000 units per meal are not recommended.

There is little evidence regarding the optimal dosage form and administration of pancreatic enzyme supplements. Most studies have compared them to placebo rather than to other enzyme products and have used quantitation of fat absorption or elimination rather than weight gain as a primary measure of efficacy.[117] Although they improve fat absorption, they may not completely eliminate steatorrhea.[117,118] However, they improve the quality of life of patients with chronic pancreatitis.[119] Since most exogenous lipase is rapidly and irreversibly destroyed at low intragastric pH, enteric-coated products are preferred for the treatment of malabsorption and steatorrhea 9. The enteric coating dissolves at a pH greater than 5.5, which allows a sufficient quantity of enzymes to remain intact until dissolution of the coating in the duodenum.[11] However, enzymes must also be emptied from the stomach into the duodenum at the same rate and time as ingested food. The size of the enteric-coated enzyme preparation influences the rate of enzyme delivery to the duodenum.[4,11] Likewise, the administration time relevant to a meal influences the timing of enzyme delivery. Products that contain enzymes in small enteric-coated microspheres or minimicrospheres are often the best products because they are thought to mix effectively with chyme, thus leaving the stomach at a similar rate.[11] Also, the optimal administration time of enzymes containing minimicrospheres appears to be either with a meal or just after.[4,120]

Despite enzyme therapy patients may continue to have steatorrhea and fail to gain sufficient weight. Compliance should be assessed in these patients as the number of capsules required with each meal can lead to noncompliance. Alternative products with higher lipase content can be tried in order to reduce the number of capsules needed. If this fails the dose of lipase should be increased. Finally, addition of an antisecretory agent may be tried to increase the availability of active enzymes in the duodenum.[121]

TABLE 46-9 Commercially Available Pancreatic Enzyme (Pancrelipase) Preparations

Product	Enzyme Content per Unit Dose (USP Units)		
	Lipase	*Amylase*	*Protease*
Enteric-coated microspheres			
Ultrase	4,500	20,000	25,000
Enteric-coated microspheres with bicarbonate buffer			
Pancrecarb MS-4	4,000	25,000	25,000
Pancrecarb MS-8	8,000	40,000	45,000
Pancrecarb MS-16	16,000	52,000	52,000
Enteric-coated minimicrospheres			
Creon 6,000 lipase units[a]	6,000	30,000	19,000
Creon 12,000 lipase units[a]	12,000	60,000	38,000
Creon 24,000 lipase units[a]	24,000	120,000	76,000
Enteric-coated minitablets			
Ultrase MT 12	12,000	39,000	39,000
Ultrase MT 18	18,000	58,500	58,500
Ultrase MT 20	20,000	65,000	65,000

USP, United States Pharmacopeia.
[a]FDA-approved product.

Pancreatic Enzyme Supplements Until recently none of the commercially available pancreatic enzyme supplements were approved by the FDA because they predated enactment of the Food, Drug, and Cosmetic Act of 1938. Since the FDA announced in 2004 that all products would have to seek approval only one has been approved and three others have submitted new drug applications.[122] Dosage forms of products currently available in the United States include enteric-coated microspheres, bicarbonate-buffered microspheres, enteric-coated minimicrospheres, and enteric-coated minitablets encased in a cellulose or gelatin capsule (Table 46–9). Enzymes are easily administered to patients able to swallow the capsules or their contents. However, administration to patients with enteral feeding tubes presents a challenge. Products containing microspheres may be administered through feeding tubes in an applesauce or apple juice mixture.[11] Clinicians must be aware, however, that available products are not equivalent and should consider this before substituting products in patients who require administration through a nonoral route.

Adverse reactions from pancreatic enzyme supplements are generally benign. High doses can lead to nausea, diarrhea, and intestinal upset.[11] One of the more serious adverse effects of these products is fibrosing colonopathy. It occurs when the enzymes cause deposition of fibrin in the colon, leading to colonic stricture. This reaction is uncommon and has been reported mostly in children with cystic fibrosis who received high doses of enzymes for prolonged periods.[11] Certain enteric coatings may specifically invoke this reaction. Another concern with pancreatic enzymes is the risk of possible viral infection due to contamination of these porcine-derived products.[122] Finally, pancreatic enzymes have been associated with deficiencies in fat-soluble vitamins, and appropriate monitoring and supplementation, especially of vitamin D, should be instituted.[4,81]

Adjuncts to Enzyme Therapy The addition of a histamine$_2$-recpetor antagonist or proton pump inhibitor to pancreatic enzyme supplementation may increase the effectiveness of enzyme therapy for malabsorption and steatorrhea ⑩. The beneficial effects of these agents result from an increase in gastric and duodenal pH.[11,81] This is thought to result in an increase in the amount of active enzymes available in the duodenum. Traditionally, their use has been advocated with non-enteric-coated enzyme products.[4,11] However, their use in combination with enteric-coated preparations results in similar efficacy between standard and low-dose enzyme regimens.[121]

PHARMACOECONOMIC CONSIDERATIONS

The pharmacoeconomic issues associated with the medical treatment of acute pancreatitis and chronic pancreatitis have not been extensively examined. Aggressive medical and surgical care decreases mortality in acute pancreatitis, but the overall cost-effectiveness of a specific treatment is unknown. The relief of abdominal pain in acute pancreatitis and chronic pancreatitis, as well as pancreatic enzyme supplementation in patients with chronic pancreatitis, improves quality of life and nutritional status.[119,123]

With so few FDA-approved pancreatic enzyme supplements currently available pricing should remain fairly competitive. However, if cost is based on the total number of capsules per day, rather than the cost of a single capsule, high-potency preparations may help minimize cost. The addition of a histamine$_2$-receptor antagonist or proton pump inhibitor may actually be cost-effective for patients with chronic pancreatitis who are inadequately controlled on maximal enzyme therapy. They reduce the amount of enzymes needed and they may improve efficacy.[121]

EVALUATION OF THERAPEUTIC OUTCOMES

ACUTE PANCREATITIS

Hydration status, serum electrolytes, pain control, and nutritional status should be assessed periodically in patients with mild acute pancreatitis, depending on the degree of abdominal pain and fluid loss. Patients with severe acute pancreatitis should receive intensive care and close monitoring of vital signs, fluid and electrolyte status, white blood cell count, blood glucose, lactate dehydrogenase, aspartate aminotransferase, serum albumin, hematocrit, blood urea nitrogen, serum creatinine, and international normalized ratio. Continuous hemodynamic and arterial blood gas monitoring is essential. Serum lipase, amylase, and bilirubin require less frequent monitoring. The patient should also be monitored for signs of infection, relief of abdominal pain, and adequate nutritional status. Severity of disease and patient response should be assessed using an evidence-based method, for example APACHE II.

CHRONIC PANCREATITIS

The severity and frequency of abdominal pain should be assessed periodically in patients with chronic pancreatitis using a standardized scale to determine the efficacy of pain therapy. Patients receiving opioids should be prescribed scheduled bowel regimens and be monitored for constipation. Patients receiving pancreatic enzymes for malabsorption should have their weight and stool frequency and consistency monitored periodically. More objective assessments of fecal fat content, such as the ^{13}C-mixed triglyceride breath test, can be utilized but are usually unnecessary and impractical in general clinical practice.[4,98,124] Blood glucose must be closely monitored in patients with diabetes mellitus, and those with long-standing disease should receive appropriate monitoring for nephropathy, retinopathy, and neuropathy.[4]

ACKNOWLEDGMENT

The authors wish to acknowledge the contributions of Rosemary R. Berardi, Pharm.D., FCCP, FASHP, to previous editions of this chapter.

CHAPTER 47

Viral Hepatitis

PAULINA DEMING

KEY CONCEPTS

1. Hepatitis A is transmitted via the fecal–oral route. Transmission is most likely to occur through travel to countries with high rates of hepatitis A, poor sanitation and hygiene, and overcrowded areas.
2. Hepatitis A causes an acute, self-limiting illness and does not lead to chronic infection. There are three stages of infection: incubation, acute hepatitis, and convalescence. Rarely, the infection progresses to liver failure.
3. Treatment of hepatitis A consists of supportive care. There is no role for antiviral agents in treatment.
4. Hepatitis B causes both acute and chronic infection. Infants and children are at high risk for chronic infection.
5. Several therapies are available for hepatitis B, including lamivudine, interferon α2b, pegylated interferon α2a, entecavir, adefovir, telbivudine, and tenofovir. Patient status, extent of disease, viral load, and viral resistance are all considered when deciding on treatment.
6. Chronic hepatitis B patients may require long-term therapy. Long-term therapy poses a challenge because of the potential for developing resistance. Resistance to lamivudine and telbivudine is most common, although resistance mutations to adefovir and entecavir have also been seen. Optimal treatment of resistant strains is unknown.
7. Prevention of hepatitis B infections focuses on immunization of all children and at-risk adults.
8. Hepatitis C is an insidious, blood-borne infection. Injection drug use is the major mode of transmission in the United States.
9. Combination pegylated interferon and ribavirin therapy is the treatment of choice for hepatitis C. Treatment duration for hepatitis C infections is 48 weeks for viral genotype 1, and 24 weeks for genotypes 2 and 3. However, therapy may be optimized based on infecting genotype and virologic response. Viral genotype 1 is most difficult to treat.
10. Side effects of hepatitis C therapy pose a significant obstacle to completion of therapy and chance for cure. Adjunct pharmacologic therapy and dose reductions may be necessary to prevent premature cessation of treatment.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

The major hepatotrophic viruses responsible for viral hepatitis are hepatitis A, hepatitis B, hepatitis C, delta hepatitis, and hepatitis E. All share clinical, biochemical, immunoserologic, and histologic findings. Both hepatitides A and E are spread through fecal–oral contamination; whereas hepatitides B, C, and delta are transmitted parenterally. Infection with delta hepatitis requires coinfection with hepatitis B. Although the rates of acute infection have declined, viral hepatitis remains a major cause of morbidity and mortality with a significant impact on healthcare costs in the United States. Significant therapeutic advances have occurred with hepatitis B with the approval of new agents and updated guidelines for care. For hepatitis C, the challenge remains of increasing successful outcomes while minimizing side effects of therapy. This chapter focuses on hepatitides A, B, and C.

HEPATITIS A

Hepatitis A virus (HAV), or infectious hepatitis, is often a self-limiting and acute viral infection of the liver posing a health risk worldwide. The infection is rarely fatal. According to the Centers for Disease Control and Prevention (CDC), the 2,979 reported cases of acute clinical hepatitis A infection in the United States in 2007 were the lowest in recorded history.[1] Although vaccine preventable, HAV continues to be one of the most commonly reported infections.

EPIDEMIOLOGY

Various patient groups are at increased risk for infection with HAV. Children pose a particular problem with the spread of the disease because they often remain clinically asymptomatic and are infectious for longer periods of time than adults. Traditionally, the most likely patient group affected is household or close personal contacts of an infected person. 1 Infection primarily occurs through the fecal–oral route, by person-to-person, or by ingestion of contaminated food or water. Incidentally, HAV's prevalence is linked to regions with low socioeconomic status and specifically to those with poor sanitary conditions and overcrowding. Rarely, the virus can be spread through blood or blood products. Despite being detectable in saliva, there are no data to suggest transmission through this mode of contact.[2] International travel and immigration also mitigate potential exposure to the virus.

International travel, in particular travel to HAV endemic areas, continues to be a major risk factor for HAV infection. Although rates have declined as a result of successful vaccination programs to a record low of 1.0 cases per 100,000 people in 2007, the proportion

of HAV rates among international travelers continues to rise. Other identified risk factors include sexual and household contact with a HAV infected person, men who have sex with men (MSM), and injection drug users (IDUs).[1] Additional patient groups that are at risk include patients with chronic liver disease and persons working with nonhuman primates. For half of all identified HAV cases in 2007, no risk factor was identified.[1] In pregnant women, acute HAV infection may be associated with maternal complications and preterm labor.[3] Food-borne outbreaks also occur; a 2003 outbreak in Pennsylvania was associated with more than 500 persons infected and 3 deaths, and was linked to green onions imported from Mexico.[4]

HAV infections acquired through international travel create significant HAV-associated costs in terms of loss of work time and healthcare costs. Despite low endemic rates and successful vaccinations of at-risk populations in the United States, unvaccinated children acquiring HAV infections abroad can serve as reservoirs of the virus upon return to the United States, even while remaining clinically asymptomatic themselves. Nearly 40% of children younger than age 15 years with HAV had international travel as a risk factor in 2004.[1] According to the CDC, the majority of travel-related cases correspond to travel to Central and South America and Mexico.[1] Most Americans traveling to Mexico do not consider that country to be a risk in part because of Mexico's proximity to the United States. Moreover, most tourists falsely believe that higher-end resorts imply safety and that short visits to foreign countries are not associated with a risk for infection. In fact, frequent, short visits will have a cumulative risk for infection that should not be ignored.[6]

ETIOLOGY

Hepatitis A is a RNA virus belonging to the genus *Hepatovirus* of the *Picornaviridae* family. Humans are the only known reservoir for the virus and transmission occurs primarily through the fecal–oral route.[7] The virus is stable in the environment for at least a month and requires heating foods to a minimum of 85°C (185°F) for 1 minute or disinfecting with a 1:100 dilution of sodium hypochlorite (bleach) in tap water for inactivation.[2,8]

Multiple genotypes of the virus exist and although the clinical implications of infection by particular type are unknown, types I and III are the most commonly identified in human outbreaks.[7]

PATHOPHYSIOLOGY

HAV infection is usually acute, self-limiting, and confers lifelong immunity. HAV's life cycle in the human host classically begins with ingestion of the virus. Absorption in the stomach or small intestine allows entry into the circulation and uptake by the liver. Replication of the virus occurs within hepatocytes and gastrointestinal epithelial cells. New virus particles are released into the blood and secreted into bile by the liver. The virus is then either reabsorbed to continue its cycle or excreted in the stool. The enterohepatic cycle will continue until interrupted by antibody neutralization.[7] The exact mechanism of replication and secretion is unknown; however, the initial viral expansion does not seem to be associated with hepatic injury as peak viral fecal excretion precedes clinical signs and symptoms of infection.[2]

On biopsy, acute hepatitis is marked by hepatocellular degeneration, inflammatory infiltrate, and hepatocyte regeneration. Hepatocellular degeneration occurs as a result of immune-mediated injury and not as a direct cytopathic effect of the virus.[9] Clinical symptoms of HAV typically identify the onset of the immune response. Cytolytic T cells mediate hepatocyte lysis to eradicate the virus and mark the cellular immune response with rising hepatic enzyme levels.[7]

TABLE 47-1 Clinical Presentation of Acute Hepatitis A

Signs and symptoms
- The preicteric phase brings nonspecific influenza-like symptoms consisting of anorexia, nausea, fatigue, and malaise
- Abrupt onset of anorexia, nausea, vomiting, malaise, fever, headache, and right upper quadrant abdominal pain with acute illness
- Icteric hepatitis is generally accompanied by dark urine, acholic (light-colored) stools, and worsening of systemic symptoms
- Pruritus is often a major complaint of icteric patients

Physical examination
- Icteric sclera, skin, and secretions
- Mild weight loss of 2–5 kg
- Hepatomegaly

Laboratory tests
- Positive-serum immunoglobulin M anti-hepatitis A virus
- Mild elevations of serum bilirubin, γ-globulin, and hepatic transaminase (alanine transaminase and aspartate transaminase) values to about twice normal in acute anicteric disease
- Elevations of alkaline phosphatase, γ-glutamyl transferase, and total bilirubin in patients with cholestatic illness

CLINICAL PRESENTATION

2 The incubation period of HAV is approximately 28 days, with a range of 15 to 50 days. Viremia occurs within 1 to 2 weeks of exposure as patients begin to shed the virus.[2] Table 47–1 summarizes the clinical features of acute hepatitis A. Peak fecal shedding of the virus precedes the onset of clinical symptoms and elevated liver enzymes. Acute hepatitis follows, beginning with the preicteric or prodromal period. The phase is marked by an abrupt onset of nonspecific symptoms, some very mild.[2] Other, more unusual symptoms include chills, myalgia, arthralgia, cough, constipation, diarrhea, pruritus, and urticaria. The phase generally lasts 2 months. There are no specific symptoms unique to HAV. Liver enzyme levels rise within the first weeks of infection, peaking approximately in the fourth week and normalizing by the eighth week. Conjugated bilirubinemia, or dark urine, precedes the onset of the icteric period. The concentration of virus declines at this point and patients are generally considered noninfectious approximately 1 week after the onset of jaundice.[10] Gastrointestinal (GI) symptoms may persist or subside during this time and some patients may have hepatomegaly. Duration of the icteric period varies and corresponds to disease duration. It averages between 7 and 30 days.[7]

Symptoms and severity of HAV vary according to age. Children younger than 6 years of age typically are asymptomatic. Symptoms, if they do occur, do not include jaundice. In older children and adults, the majority of patients present with symptoms that last less than 2 months and 70% of adults experience jaundice. Peak viral shedding precedes the onset of GI symptoms in adults. In young children, shedding can occur for months following diagnosis.[2] Because children are often asymptomatic and will shed the virus for long periods of time they can serve as a reservoir for the spread of HAV.

HAV RNA is detectable in the serum for an average of 17 days before peak alanine aminotransferase (ALT) levels and can persist for an average of 79 days after the onset of symptoms. In some patients, serum HAV is detectable for more than a year.[11] Immunoglobulin (Ig) M antibody to HAV (anti-HAV) is required for a diagnosis of acute infection. Serum HAV becomes detectable 5 to 10 days before the onset of symptoms and can persist for months. IgG anti-HAV replaces IgM and indicates host immunity following the acute phase of the infection. Serologic tests exist but should be interpreted with caution.[8] FDA-approved assays for serologic testing detect IgM and total anti-HAV (IgG and IgM). Patients who have detectable total anti-HAV and a negative IgM have resolved

their infection. Although patients who are successfully immunized will have IgG, assays are not sensitive enough to detect anti-HAV in most patients. Similarly, patients who receive intramuscular (IM) Ig will also have anti-HAV but concentrations are below the level of detection of most assays.[2,8] Concentrations of antibody often fall to 10 to 100 times lower than what would be expected after a natural course of infection. Although a positive anti-HAV result confirms protection, undetectable concentration of anti-HAV may not necessarily imply that protective levels were not achieved.[8]

HAV does not lead to chronic infections. Some patients may experience symptoms for up to 9 months. Rarely, patients experience complications from HAV, including relapsing hepatitis, cholestatic hepatitis, and fulminant hepatitis. Fatalities from HAV are generally rare though more likely in patients older than age 50 years and in persons with preexisting liver disease.[8] Fulminant hepatitis occurs mostly in young children and adults with chronic liver disease. Although occurring in 0.01% of clinical infections, fulminant hepatitis has a high fatality rate and therapy consists of supportive care.[9]

Diagnosis

A diagnosis of HAV is based on clinical criteria of an acute onset of fatigue, abdominal pain, loss of appetite, intermittent nausea and vomiting, jaundice or elevated serum aminotransferase levels, and serologic testing for IgM anti-HAV. Serologic testing is necessary to differentiate the diagnosis from other types of hepatitis.

TREATMENT

Hepatitis A Virus

DESIRED OUTCOME

3 The majority of people infected with HAV can be expected to fully recover without clinical sequelae.[7] Nearly all individuals will have clinical resolution within 6 months of the infection, and a majority will have done so by 2 months. Rarely, symptoms persist for longer or patients relapse. The ultimate goal of therapy is complete clinical resolution. Other goals include reducing complications from the infection, normalization of liver function, and reducing infectivity and transmission.

GENERAL APPROACH TO TREATMENT

No specific treatment options exist for HAV infections. Instead, patients should receive general supportive care. In patients who develop liver failure, transplant is the only option. Although hepatocellular damage occurs through immune-mediated responses, steroid use is not recommended.[12] Prevention and prophylaxis are key to managing the virus. The importance of good hand hygiene cannot be overemphasized in preventing disease transmission. Immunoglobulin is used for pre- and postexposure prophylaxis, and offers passive immunity. Active immunity is achieved through vaccination. Vaccines were approved for use in 1995 and implemented in the routine vaccination of children, as well as at-risk adults, to reduce the overall incidence of HAV.[8]

Prevaccination serologic testing to determine susceptibility is generally not recommended. In some cases, testing may be cost effective if the cost of the test is less than that of the vaccine and if the person is from a moderate to high endemic area and likely to have prior immunity. Prevaccination serologic testing of children is not recommended. Similarly, because of high vaccine response, postvaccine serologic testing is not recommended.[8]

TABLE 47-2 Recommendations for Hepatitis A Virus (HAV) Vaccination

All children at 1 year of age
Children and adolescents age 2–18 y who live in states or communities where routine hepatitis A vaccination has been implemented because of high disease incidence
Persons traveling to or working in countries that have high or intermediate endemicity of infection[a]
Men who have sex with men
Illegal drug users
Persons with occupational risk for infection (e.g., persons who work with HAV-infected primates or with HAV in a research laboratory)
Persons who have clotting factor disorders
Persons with chronic liver disease

[a] Travelers to Canada, Western Europe, Japan, Australia, or New Zealand are at no greater risk for infection than they are in the United States. All other travelers should be assessed for HAV risk.

From Centers for Disease Control and Prevention.[8,13]

PREVENTION OF HEPATITIS A

HAV is easily preventable with vaccination. Because children often serve as reservoirs of the disease, vaccine programs have targeted children as the most effective means to control HAV. Two vaccines for HAV are available and are incorporated into the routine childhood vaccination schedule. In October 2005, the FDA reduced the minimum age for the vaccines to 12 months of age. In response, the Advisory Committee on Immunization Practices recommended expanding vaccine coverage to all children, including catch-up programs for children living in areas without existing vaccination programs. The new recommendations were enacted in the attempt to further reduce HAV incidence rates and possibly to eradicate the virus.[13] In 2007, the U.S. Department of Health and Human Services issued a health advisory after receiving reports of HAV from international adoptees. Guidelines for international adoptees and their adoptive parents are available from the CDC. Adult vaccination recommendations also exist (Table 47–2).

Routine prevention of HAV transmission includes regular hand washing with soap and water after using the bathroom, changing a diaper, and before food preparation. For travelers to countries with high endemic rates of HAV, even short-term stays in urban and upscale resorts are not risk free.[8] In particular, contaminated water and ice, fresh produce, and any uncooked foods pose a risk.[7]

Vaccines to Prevent Hepatitis A

Two inactivated virus vaccines are currently licensed in the United States: Havrix and Vaqta. Both vaccines are inactivated virus and are available for pediatric and adult use. The differences in the two vaccines are in the use of a preservative and in expression of antigen content. Vaqta is formulated without a preservative and uses units of HAV antigen to express potency. Havrix uses 2-phenoxyphenol as a preservative and antigen content is expressed as enzyme-linked immunosorbent assay units. Pediatric dosing is indicated for children 12 months of age through 18 years of age, and adult dosing is for patients ages 19 years and older (Table 47–3).[8] Although high seroconversion rates of ≥94% are achieved with the first dose, both vaccines recommend a booster shot to achieve the highest possible antibody titers. In situations of postexposure prophylaxis, previously only immunoglobulin was indicated but recent guidelines changes allow the use of vaccines for this indication. The change to the use of the vaccine is advantageous as vaccination confers the benefit of long-term immunity against HAV.[13] Both vaccines may be given concomitantly with immunoglobulin and the two brands are interchangeable for booster shots.[8]

TABLE 47-3 Recommended Dosing of Havrix and Vaqta

Vaccine	Age (y)	Dose	No. of Doses	Schedule (mo)
Havrix	1–18	720 ELISA units	2	0, 6–12
	≥19	1,440 ELISA units	2	0, 6–12
Vaqta	1–18	25 units	2	0, 6–18
	≥19	50 units	2	0, 6–18

ELISA, enzyme-linked immunoabsorbent assay.
From Centers for Disease Control and Prevention.[13]

Vaccine efficacy may be reduced in certain patient populations. In HIV (human immunodeficiency virus)-infected patients, greater immunogenic response may correlate with higher baseline CD4 cell counts. Response to the HAV vaccine as determined by detection of anti-HAV after vaccination found that among HIV patients, females and patients with CD4 counts >200 cells/mm^3 at vaccination had a higher response rate.[16]

The most common side effects of the vaccines include soreness and warmth at the injection site, headache, malaise, and pain. Reported serious adverse events include anaphylaxis, Guillain-Barré syndrome, brachial plexus neuropathy, transverse myelitis, multiple sclerosis, encephalopathy, and erythema multiforme. However, causality of these reported events has not been established. Furthermore, incidence of serious adverse events in the vaccinated population did not differ from the incidence in nonvaccinated populations. It is important to note that more than 65 million doses of the vaccine have been administered and despite routine monitoring for adverse events, there are no data to suggest a greater incidence of serious adverse events among vaccinated people compared with nonvaccinated. The vaccine is considered safe.[8]

Twinrix is a bivalent vaccine for hepatitides A and B that was approved by the FDA in 2001. The vaccine is approved for people ages 18 and older and is given at 0, 1, and 6 months. Although seroconversion exceeds 90% for HAV after the first dose, the full three-dose series is required for maximal hepatitis B virus (HBV) seroconversion. An accelerated dosing schedule is available but requires a total of four doses for optimal response. The combined vaccine offers the advantage of immunization against both types of hepatitis in a single vaccine.

Immunoglobulin

Ig is used when pre- or postexposure prophylaxis against HAV infection is needed in persons for whom vaccination is not an option. Immunoglobulin is preferred for children <12 months of age and for postexposure prophylaxis in patients aged >40 years, patients with chronic liver disease, and persons allergic to any part of the vaccine. A sterile preparation of concentrated antibodies against HAV, Ig provides protection by passive transfer of antibody. Ig is most effective if given in the incubation period of the infection. Receipt of Ig within the first 2 weeks of infection will reduce infectivity and moderate the infection in 85% of patients. Patients who receive at least 1 dose of the HAV vaccine at least 1 month earlier do not need pre- or postexposure prophylaxis with Ig.[8] Ig is available both as an intravenous (IV) and IM injection but for HAV exposure, only the IM is used. If given to infants or pregnant women, the thimerosal-free formulation should be used.

International travelers are the major patient population receiving preexposure prophylaxis with Ig. HAV vaccination or prophylaxis with Ig is recommended for travelers to countries with high endemic rates of HAV. Serious adverse events are rare. Anaphylaxis has been reported in patients with Ig A deficiency. Patients who had an anaphylaxis reaction to Ig should not receive it. There is no contraindication for use in pregnancy or lactation.

Dosing of Ig is the same for adults and children. For postexposure prophylaxis and for short-term preexposure coverage of <3 months, a single dose of 0.02 mL/kg is given intramuscularly. For long-term preexposure prophylaxis of ≤5 months, a single dose of 0.06 mL/kg is used. Either the deltoid or gluteal muscle may be used. In children younger than 24 months of age, Ig can be given in the anterolateral thigh muscle.[8]

For people who were recently exposed to HAV and who had not been previously vaccinated, Ig is indicated in the following situations: (a) when in close personal contact with an HAV-infected person; (b) all staff and attendees of daycare centers when HAV is documented; (c) if they were involved in a common source exposure; for example, in a food-borne outbreak with an HAV-infected food handler, other food handlers at the location should receive Ig; if the case person handled food and had poor hygiene or diarrhea, patrons of the location should also receive Ig if they can be identified and located within the 2 weeks of the exposure; (d) classroom contacts of an index case patient; and (e) schools, hospitals, and work settings where close personal contact occurred with the case patient.[8]

Ig can be given concomitantly with the HAV vaccine. Although the antibody titer will be lower than if the vaccine were administered alone, the response is still protective. However, Ig can interfere with the response of other vaccines and should be delayed. The measles, mumps, and rubella (MMR) vaccine should be delayed for a minimum of 3 months after receipt of Ig. The varicella vaccine must be delayed for 5 months. Conversely, Ig should not be given to patients who received the MMR within 2 weeks or the varicella vaccine within 3 weeks. In situations where the benefits of Ig outweigh the benefits of the other vaccines, revaccination can be performed after Ig administration. For the MMR, revaccination should be at least 3 months later, and for the varicella vaccine, at least 5 months later.[8] In general, Ig does not interfere with inactivated vaccines and may be administered safely with other vaccines traditionally given to travelers to some developing countries, such as the oral poliovirus or yellow fever vaccine.[8]

PHARMACOECONOMIC CONSIDERATIONS

Although the costs of an HAV outbreak are significant, routine vaccination of all individuals is not cost-effective. Rather, by targeting at-risk populations, the majority of cases can be prevented. Children play a pivotal role in disease persistence. The use of the HAV vaccine is cost-effective in children and offers the most benefit to the personal contacts of children, reflecting the role of children as a reservoir for the disease.[16] The use of the combined HAV-HBV vaccine is effective in reducing costs associated with HAV among persons who are at increased risk for infection. Among 100,000 healthcare workers in high endemic states, the vaccine was anticipated to reduce the number of related work loss days from 34,463 to 4,667 days, an estimated savings of $6.1 million.[16] Nearly $2 million in savings could be seen in costs associated with HAV treatment. In a sexually transmitted diseases clinic serving 1 million patients, the combined vaccine was expected to prevent 2,263 occult infections and cost $13,397 per quality-adjusted life-year (QALY).[17] Both studies predicted between $2 million and $2.5 million in savings associated with HAV treatment, realized mostly in reduced hospitalizations. The risk of HAV from food transmission in the United States is low and can be avoided in many cases by adherence to basic hygiene practices.

HEPATITIS B

Although a vaccine was made available in 1981, HBV has acutely infected more than 2 billion people globally, leading to chronic infection in more than 350 million people.[18] Chronic infection

with HBV is a major public health issue as it serves as a reservoir for continued HBV transmission and poses a significant risk of death resulting from liver disease. More than 1 million people per year die as a result of liver cirrhosis and hepatocellular carcinoma(HCC).

EPIDEMIOLOGY

According to the CDC, only 12% of the global population lives in an area of low prevalence for hepatitis B, defined as an area where <2% of the population is HBsAg (hepatitis B surface antigen)-positive.[18] Prevalence can vary regionally; however, areas commonly associated with high infectivity rates include sub-Saharan Africa, most of Asia, as well as the Amazon and southern parts of Eastern and Central Europe.[18] Areas of high prevalence, approximately 45% of the global population, are of special concern because most infections are of infants and children and >90% of cases lead to a chronic carrier state. Although less than 1% of people have chronic infection in both Western Europe and North America,[18] in the United States HBV is the second most common type of acute viral hepatitis and the third most reported preventable disease, second only to HAV.[19] Rates of infection in the South are highest, however overall rates of infection in the United States continue to decline. There are approximately 1.25 million chronically infected HBV people in the United States. In 2007, an estimated 43,000 people developed new infections. Annually, 3,000 to 5,000 people die from chronic liver disease attributable to HBV.[1]

HBV is transmitted sexually, parenterally, and perinatally. In areas of high HBV prevalence, perinatal transmission from mother to infant is most common, whereas in areas of intermediate prevalence, horizontal transmission from child to child is most common. Sexual contact, both homosexual and heterosexual, and injection drug use are the predominant forms of transmission in low-endemic countries such as the United States.[20] Concentration of HBV is high in blood, serum, and wound exudates of infected persons. The virus is detectable in moderate quantities in semen, vaginal fluid, and saliva, and is present in low concentrations in urine, feces, sweat, tears, and breast milk.[19,21] Transmission can occur through contact with infected body fluids in the absence of blood, as the virus may be stable in the environment for a number of days.[21,22] In the United States in 2007, no risk factor could be identified for the majority of acute infections with HBV. Among patients with identifiable risk factors, the most common risk was sexual contact, specifically multiple sexual partners, MSM, and sexual contact with a known HBV-positive person. Sexual contact was a consistent risk among all patients but especially among those aged 45 years or younger. Other known risk factors include IDU and household contact of HBV-positive person. A previously identified risk includes international travel, and was the largest overall risk factor in 2004 among children younger than 15 years of age.[5] No cases were documented for patients receiving transfusions or on hemodialysis.[18] Among racial and ethnic groups, HBV is highest among non-Hispanic blacks. Hispanics and non-Hispanic whites have similarly low rates, while Asians/Pacific Islanders have the lowest HBV rates.[5]

The mode of transmission has clinical implications because chronic infections are associated with infection acquired in younger patients, especially those infected perinatally and in early childhood.[21]

ETIOLOGY

The HBV is a DNA virus of the family *Hepadnaviridae*. It is a partially double-stranded, circular DNA with 3,200 base pairs that typically infects liver cells, although it has been found in kidney, pancreas, and mononuclear cells.[23,24] Seven HBV genotypes exist (A to H) with distinct geographic distribution (Table 47–4). It is possible that genotype prevalence may be dependent on mode of transmission as types B and C are found in areas where vertical transmission is the primary mode of infection.[25] Correlations between clinical outcomes and HBV genotypes have been suggested, with genotype C associated with more severe liver injury, including liver cirrhosis and progression to HCC.[25] Noted limitations of studies are frequently small sample sizes and a predominance of research from Asia, primarily comparing genotypes B and C.[25] Nonetheless, a study of a diverse patient immigrant population infected with genotypes A, B, C, D, and E, confirmed that more severe liver fibrosis was significantly higher in HBV genotypes A, C, and D-infected patients. Genotype B may be more benign because it is associated with faster seroconversion, although clinical studies suggest genotype A may have equivalent, if not higher rates of seroconversion.[26,27] Resistance mutations may contribute to genotype virulence and hence impact severity of liver disease in infection.[28]

TABLE 47-4 Worldwide Distribution of Hepatitis B Virus Genotypes

Genotype	Geographic Distribution
A	Northern/Central Europe, North America, sub-Saharan Africa
B, C	Southeast Asia, Japan
D	Mediterranean region, Middle East, India
F	Central and South America, North American Indians, Polynesia
G	France, North America
H	Central America

Data from Ganne-Carrie N, Williams V, Kaddouri H, et al. Significance of hepatitis B virus genotypes A to E in a cohort of patients with chronic hepatitis B in the Seine Saint Denis district of Paris (France). J Med Virol 2006;78:335–340.

PATHOPHYSIOLOGY

Upon infection, replication of the virus begins by attachment of the virion to the hepatocyte cell surface receptors. The particles are transported to the nucleus where the DNA is converted into closed, circular DNA that serves as a template for pregenomic RNA. Viral RNA is then transcribed and transported back to the cytoplasm where it can alternatively serve as a reservoir for future viral templates or bud into the intracellular membrane with the viral envelope proteins and infect other cells.[23,27] The viral genome has four reading frames coding for various proteins and enzymes required for viral replication and spread. Several of these proteins are used diagnostically (Table 47–5). The HBsAg is the most abundant of the three surface antigens and is detectable at the onset of clinical symptoms. Its persistence past 6 months after initial detection corresponds to chronic infection and poses an increased risk for cirrhosis, hepatic decompensation, and HCC. Development of antibody to HBsAg (anti-HBsAg) confers immunity to the virus and clearance of HBsAg is associated with favorable outcomes.[24,29] The precore polypeptide encodes for the secretory protein hepatitis B e antigen (HBeAg) and the hepatitis B core antigen (HBcAg) proteins. Although HBeAg's role in infection is nebulous, it is present in an acute infection and is replaced by antibodies (anti-HBeAg) once an infection is resolved. HBeAg was assumed to be a marker of viral replication and infectivity; however, it is now known that some viral mutants exist that are unable to have or have downregulated expression of HBeAg, although their ability to replicate is not affected.[27] HBeAg-negative mutants pose a particular clinical challenge because they are refractory to treatment. The HBcAg is a nucleocapsid protein that, when expressed on hepatocytes, promotes immune-mediated cell death. High levels of antibodies (IgM anti-HBcAg) are detectable during acute infections. The detection of IgM anti-HBcAg is also a reliable assay for diagnosing fulminant acute hepatitis where HBsAg and

TABLE 47-5 Interpretation of Serologic Tests in Hepatitis B Virus

Tests	Result	Interpretation
HBsAg	(–)	
Anti-HBc	(–)	Susceptible
Anti-HBs	(–)	
HBsAg	(–)	
Anti-HBc	(+)	Immune because of natural infection
Anti-HBs	(+)	
HBsAg	(–)	Immune because of vaccination (valid only if test performed 1–2 mo after third vaccine dose)
Anti-HBc	(–)	
Anti-HBs	(+)	
HBsAg	(+)	
Anti-HBc	(+)	Acute infection

HBV DNA are often undetectable.[23,30] Patients who respond to vaccine will have anti-HBsAg only.[8]

HBV itself does not seem to be pathogenic to cells; rather, it is thought that the immune response to the virus is cytotoxic to hepatocytes. Antigen nonspecific inflammatory responses triggered by T cells may be responsible for most hepatic injury, with progression to cirrhosis and HCC.[21,23] The immune response includes major histocompatibility complex (MHC) class I CD8 cytotoxic T cells and MHC class II CD4 T-helper cells. In both an acute and chronic infection, the antibody response is strong. In an acute infection, however, the cytotoxic T-cell response is critical to viral clearance. If the response is weak, chronic infection is likely.[23] Moreover, liver injury is likely caused by secondary, nonspecific inflammation activated by the initial cytotoxic lymphocyte response and as an attempt by the immune system to clear the virus by destroying HBV antigen presenting hepatocytes. Destruction of hepatocytes results in release of circulating, and hence increased, ALT levels.

Cirrhosis

Cirrhosis results as the liver attempts to regenerate while in an environment of persistent inflammation. Like in other viral hepatitis-induced cirrhoses, continued alcohol consumption exacerbates hepatocellular damage. Most patients with compensated cirrhosis are either asymptomatic or have mild symptoms of epigastric pain and dyspepsia.[26] During cirrhosis, the liver enters a cycle of ongoing liver damage, fibrosis, and attempts at regeneration. The classical appearance of a small and knobby liver reflects the irreversible effect of nodules of regenerating cells integrated with infiltrates of inflammatory induced fibrous tissue. Both viral and clinical factors affect the outcome of cirrhosis (Table 47–6). The development of cirrhosis is mostly insidious and patients can remain stable for years before disease progression. An estimated 20% of all chronic hepatitis B patients develop complications of hepatic insufficiency and portal hypertension as their compensated cirrhosis progresses

to decompensated cirrhosis within a 5-year period.[27] Typically, the initial clinical findings of decompensated cirrhosis are ascites, jaundice, variceal bleed, encephalopathy, or a combination of symptoms.[26] Damage is irreversible. Treatment is supportive care and patients are candidates for liver transplantation.

Hepatocellular Carcinoma

HBV is a known risk factor for the development of HCC and in areas of high HBV endemicity, a major complication of the infection.[21,23] The development of HCC can be insidious, occurring in the absence of cirrhosis or in the presence of clinically silent, compensated cirrhosis. Many patients with HCC have no signs of decompensated cirrhosis.[26] The virus itself is not likely the causative agent of the cancer. In most cases, HCC develops after years of inflammatory processes provoked by ongoing HBV infection. Compared to hepatitis C virus (HCV), however, HBV does seem to provoke a more direct carcinogenic effect as evidenced by its presence in less-severe liver disease, and among patients with advanced HCC, HBV infection is associated with a worse survival rate.[31] Several factors influence the development of HCC, as well as predict survival (see Table 47–6). HCC is more prevalent in males; in older patients; in patients coinfected with HCV or delta hepatitis; and in patients with serologic markings of past or present HBV infection, preexisting cirrhosis, or continued alcohol ingestion. Risks for death and decompensation increase with underlying liver disease. Other host-specific or environmental factors may impact the course of liver disease. In Asian patients, HCC tumors are commonly seen in otherwise healthy patients, whereas HCC is typically seen in white patients with chronic liver disease.[32] Persistently elevated HBV DNA levels (≥10,000 copies/mL) predict HCC development, even after adjusting for sex, age, cigarette smoking, alcohol consumption, HBeAg status, ALT level, and liver cirrhosis.[33] HBeAg status is not a risk factor. In otherwise healthy patients without coinfection or who do not have HCC or decompensation at the time of seroclearance, HBsAg seroclearance does predict a favorable long-term outcome.[29] Additional predictors of survival include younger age and maintenance of liver function as evidenced by laboratory findings.[26]

CLINICAL PRESENTATION

4 The clinical symptoms and course of an HBV infection are indistinguishable from other types of viral hepatitis. Three phases of an HBV infection exist. During the initial or acute phase of a HBV infection in adults and older children, the HBV enters a 4- to 10-week incubation period, during which antibodies toward the HBV core are produced and the virus replicates profusely. Active viral replication results in high serum HBV DNA levels and HBeAg secretion.[23] ALT levels may rise slightly, but most patients will remain asymptomatic. Symptoms, if they do occur, include fever,

anorexia, nausea, vomiting, jaundice, dark urine, clay-colored or pale stools, and abdominal pain. Most neonates and children are anicteric and have no clinical symptoms, whereas up to half of adult patients are icteric.[26] HBsAg does not become detectable until after significant viremia. The initial phase is considered immunotolerant because no hepatic injury is sustained, as evidenced by generally normal ALT levels. Patients are highly infectious during this time.[25] In perinatally acquired infections, and in young children, the phase can last for decades–until adulthood.[24] Infected children pose a particular risk because they are often asymptomatic, undiagnosed, and highly infectious.

The immunoactive phase marks a decrease in HBV DNA levels with ongoing secretion of HBeAg. Patients are symptomatic with intermittent flares of hepatitis and marked increases in ALT levels. More frequent flares are associated with disease progression.[34] The phase can last a few weeks in acute disease, and for years in patients with chronic disease. As the host immune system attempts to gain control of the infection by stopping active viral replication, serum HBV DNA levels drop to undetectable, ALT levels normalize, and liver necroinflammation resolves.[26]

If the infection is self-limiting, HBV DNA quickly subsides, HBeAg disappears within weeks, and HBsAg usually resolves within 4 months. The final phase is seroconversion and is defined by the replacement of HBeAg with anti-HBeAg. Factors favoring seroconversion include female sex, older age, biochemical activity, and genotype. Flares of hepatitis with ALT levels >5 times the upper limits of normal, compared to <5 times the upper limits of normal, correspond to increased immune system activity and precede seroconversion. Some studies suggest that the A and B genotypes are associated with earlier seroconversion than genotypes C and D but the data are inconclusive and no recommendations exist for genotype testing in clinical practice.[25,27]

Chronic HBV

4 Patients who continue to have detectable HBsAg and HBeAg and a high serum titer of HBV DNA for more than 6 months have chronic HBV.[26] Table 47–7 lists the clinical features of chronic hepatitis B. The most predictive factor for developing a chronic infection is age. Perinatal infections almost always result in chronic infections because of immune tolerance to the virus.[35] Risks of chronicity decline to a rate of 30% in infants and to less than 5% of acute adult infections.[24]

Chronic infections can be controlled in many cases, but cure is not possible because the HBV template is integrated into the host genome. In patients with recurring cycles of viral expression and host immune response, progressive liver damage ensues.[35] Patients can be divided into two types of chronic hepatitis B: those who are HBeAg-positive and those who are HBeAg-negative. The ability to express HBeAg by the virus differentiates the two types of chronic infection. Patients are considered to be in the "immune tolerant" phase when HBeAg is positive, high serum HBV DNA levels are detected, and ALT levels are normal. Typically these patients were infected early in life and develop elevated ALT levels later in life. Spontaneous HBeAg clearance is possible and is associated with older age, higher ALT, and infection with HBV genotype B.[27]

Patients who are HBeAg-negative can be further subdivided into the active or inactive carrier. HBeAg-negative chronic HBV patients who are active carriers have high serum HBV DNA, elevated ALT levels, and liver necroinflammation.[26] The clinical course tends to be worse with a very low rate of spontaneous remission. Patients may have long periods of disease remission but recurring flares of hepatitis with increased frequency and severity can progress to cirrhosis and HCC. HBeAg-negative chronic HBV patients who are inactive carriers have detectable HBsAg and anti-HBeAg, normal ALT, and either low or undetectable levels of HBV DNA. This patient population usually experiences a more benign course of disease, with the possibility of long-term remission, even seroconversion, although reactivation is possible with the progression to cirrhosis and HCC. Rarely, patients will resolve their infection. Patients with undetectable HBsAg but with anti-HBsAg and anti-HBcAg represent a small portion of patients who are not likely to experience reinfection or reactivation unless immunosuppressed.[26] Up to 20% of patients in the inactive carrier state may revert to detectable HBeAg, emphasizing the need for life-long follow-up to confirm quiescence. [27]

TABLE 47-7 Clinical Presentation of Chronic Hepatitis B[a]

Signs and symptoms
• Easy fatigability, anxiety, anorexia, and malaise
• Ascites, jaundice, variceal bleeding, and hepatic encephalopathy can manifest with liver decompensation
• Hepatic encephalopathy is associated with hyperexcitability, impaired mentation, confusion, obtundation, and eventually coma
• Vomiting and seizures
Physical examination
• Icteric sclera, skin, and secretions
• Decreased bowel sounds, increased abdominal girth, and detectable fluid wave
• Asterixis
• Spider angiomata
Laboratory tests
• Presence of hepatitis B surface antigen >6 mo
• Intermittent elevations of hepatic transaminase (alanine transaminase and aspartate transaminase) and hepatitis B virus DNA >20,000 IU/mL (10^5 copies/mL)
• Liver biopsies for pathologic classification as chronic persistent hepatitis, chronic active hepatitis, or cirrhosis

[a]Chronic hepatitis B can be present even without all the signs, symptoms, and physical examination findings listed being apparent.

HBV MUTATIONS

6 Among the DNA viruses, HBV is notable for its significantly higher mutation rate.[27] Long-term therapy is problematic because of the high likelihood of developing viral resistance. One of the most common mutations consists of a nucleotide substitution either preventing or causing downregulation of the production of HBeAg. The mutation results in a chronic infection that may have a poorer long-term prognosis. Typically, the mutation emerges during the infection and represents a later stage in the course of chronic HBV infection with more advanced liver disease. Variants in the precore or core promoter region are thought to be responsible for the mutation.[27]

The selective pressures of the L-nucleoside analog antivirals, including lamivudine, cause the YMDD mutation. The mutation is associated with the active site of the DNA polymerase and causes an altered active site. The incidence of lamivudine resistance increases with each subsequent year of therapy and may be associated with a more severe disease progression.[27] An added risk of developing resistance is the retention of the mutation within the virus even four years after lamivudine therapy.[36] Cross-resistance of lamivudine-resistant YMDD mutants to telbivudine has been demonstrated and patients treated with lamivudine and telbivudine showed resistance mutations to both drugs. Telbivudine-specific resistance can also occur at rates lower than that seen in lamivudine.[37] Other mutations include resistance to adefovir and entecavir. Resistance to adefovir is associated with substitutions of aspargine by threonine (rtN236T) and substitution of alanine by valine or threonine (rtA181V/T), as well as other

possible mutations to the HBV polymerase gene. The addition of lamivudine in adefovir resistance may overcome resistance, although the optimal management of either adefovir- or entecavir-resistant strains is not clear.[27,38]

PREVENTION OF HEPATITIS B

Despite the introduction of the HBV vaccine in 1981 and recommendations on vaccination in 1982, rates of HBV did not decline in the early 1980s. Initial declines in incidence were likely attributable to behavioral changes among high-risk groups as a result of the acquired immune deficiency syndrome (AIDS) epidemic. A 94% decline in rates between 1990 and 2004 was seen in children and adolescents, which began with the initiation of screening of pregnant women and subsequent immunizations of infants and recommendations set forth in the 1990s to immunize adolescents. Regulations enacted by Occupational Safety and Health Administration (OSHA) further reduced overall U.S. rates by 75%.[19,22]

7 Prophylaxis against HBV can be achieved by vaccination or by passive immunity in postexposure cases with hepatitis B immunoglobulin. Vaccination is the most effective strategy to prevent infection and a comprehensive vaccination strategy has been implemented in the United States (Table 47–8). Vaccines use HBsAg for the antigen via recombinant DNA technology using yeast to prompt active immunity. More than 60 million adolescents and more than 40 million infants and children have received a HBV vaccine in the United States since 1982. The vaccine is considered safe. Since 2000, vaccines licensed in the United States either contain none or trace amounts of thimerosal as a preservative. Available vaccines include two single-antigen products and three combination products. The two single-antigen products are Recombivax HB and Engerix-B. Twinrix is a combination vaccine for HAV and HBV in adults. Comvax and Pediarix are used for children and are used for HBV along with other scheduled vaccines.

Passive immunity in the form of anti-HBsAg offers temporary protection against HBV and is used in conjunction with the hepatitis B vaccine for postexposure prophylaxis.[22]

TABLE 47-8 Recommendations for Hepatitis B Virus (HBV) Vaccination

Infants
Adolescents including all previously unvaccinated children <19 y
All unvaccinated adults at risk for infection
All unvaccinated adults seeking vaccination (specific risk factor not required)
Men and women with a history of other sexually transmitted diseases and persons with a history of multiple sex partners (>1 partner/6 mo)
Men who have sex with men
Current or recent injection drug users
Household contacts and sex partners of persons with chronic hepatitis B infection and healthcare and public safety workers with exposure to blood in the workplace
Clients and staff of institutions for the developmentally disabled
International travelers to regions with high or intermediate levels (HBsAg prevalence ≥2%) of endemic HBV infection
Recipients of clotting-factor concentrates
Sexually transmitted disease clinic patients
HIV patient/HIV-testing patients
Drug-abuse treatment and prevention clinic patients
Correctional facilities inmates
Chronic dialysis/ESRD patients including predialysis, peritoneal dialysis, and home dialysis patients
Persons with chronic liver disease

ESRD, end-stage renal disease; HIV, human immunodeficiency virus.

TREATMENT

Hepatitis B Virus

DESIRED OUTCOME

HBV infections are not curable; rather, the goals of therapy are to increase the chances for seroclearance, prevent disease progression to cirrhosis and HCC, and to minimize further injury in patients with ongoing liver damage.

GENERAL APPROACH TO TREATMENT

5 Response to therapy is monitored by biochemical (normalization of ALT levels), histologic examination of liver cells from biopsy (a minimum 2-point decrease in histology activity compared with baseline biopsy), and virologic response (undetectable serum HBV DNA levels and loss of HBeAg in HBeAg-positive patients).[27] Maintenance of viral suppression is defined as durability of response. In HBeAg-positive patients, successful therapy includes loss of HBeAg status and seroconversion to anti-HBeAg. Other serologic markers are typically not evaluated in clinical trials. Recommendations for treatment consider the patient's age, serum HBV DNA and ALT levels, as well as histologic evidence and clinical progression of disease (Figs. 47–1 and 47–2). Not all chronic HBV patients are candidates for treatment. Some patients may be best managed with periodic monitoring for disease progression because the chances for therapeutic response are unlikely and do not outweigh the risks and costs associated with treatment. Various guidelines have been published and updates made as more drugs are indicated for use in HBV.[27,30,39]

NONPHARMACOLOGIC THERAPY

All chronic HBV patients should be counseled on preventing disease transmission. Sexual and household contacts should be vaccinated. To minimize further liver damage, all chronic HBV patients should avoid alcohol and be immunized against HBV. No level of alcohol use has been established as safe.[27] Moreover, patients are encouraged to consult their medical provider before using any new medications, including herbals and nonprescription drugs.[22]

Herbal medicines are an intriguing option to many patients. Four common preparations include *Phyllanthus*, milk thistle, glycyrrhizin (licorice root extract), and a mixture of herbs known as Liv 52. Although some of the products may have some benefits, the methodologic qualities of the trials evaluating the herbs are poor. Randomized, placebo-controlled studies and long-term followup data are lacking. Meta-analysis of existing studies demonstrated that milk thistle and Liv 52 do not affect the course of liver disease. Herbal treatment is not recommended for patients with chronic hepatitis B.[40]

PHARMACOLOGIC THERAPY

5 Because hepatic damage is sustained by ongoing viral replication, drug therapy aims to suppress viral replication by either immune mediating or antiviral agents. In the United States, interferon (IFN)-α2b, lamivudine, telbivudine, adefovir, entecavir, pegylated (peg) IFN-α2a, and tenofovir are all approved as first-line therapy options for chronic HBV.[27]

Interferon

Interferon-α2b therapy was the first approved therapy for treatment of HBV and improves long-term outcomes and survival.[21] Acting as a host cytokine, it has antiviral, antiproliferative, and

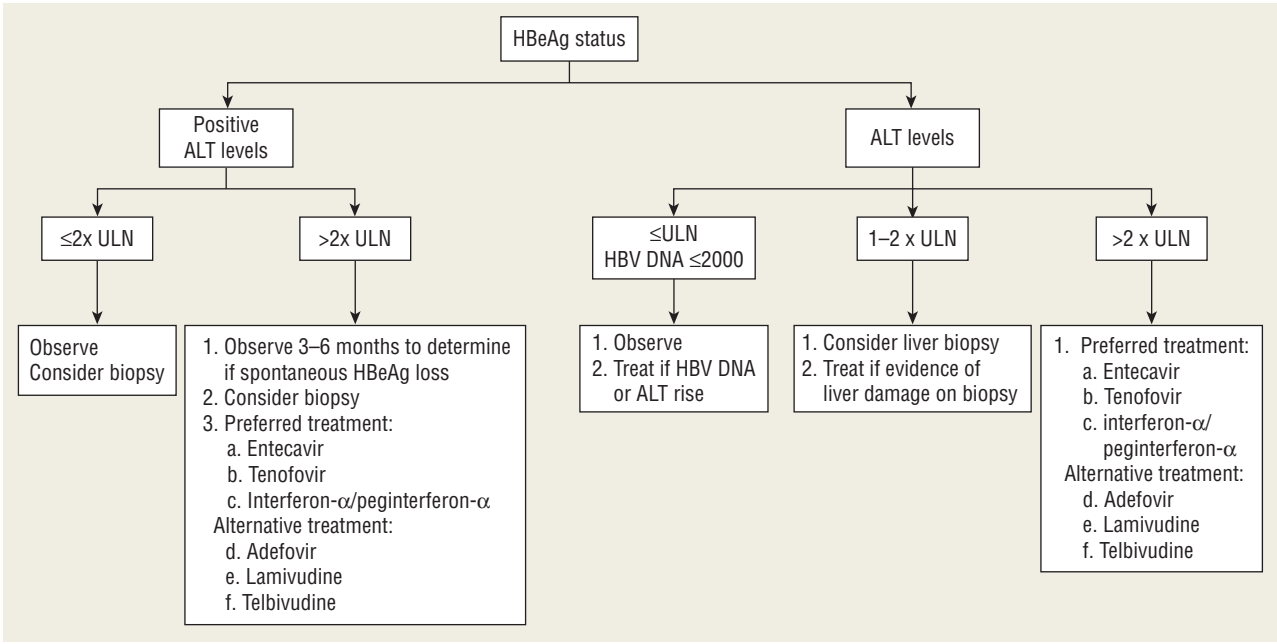

FIGURE 47-1. Suggested treatment algorithm for chronic hepatitis B virus infection based on the recommendations of the American Association for the Study of Liver Diseases. (ALT, alanine transaminases; HBeAg, hepatitis B e antigen; PegIFN, pegylated interferon.) *(Adapted from reference 27.)*

immunomodulatory effects in chronic HBV.[41] Several factors correlate with improved response to interferon therapy, including increased ALT and HBV DNA levels, high histologic activity score at biopsy, and being non-Asian. Asian patients tend to have more normal ALT levels in chronic infection, confounding the actual impact of ethnicity on infection.[41]

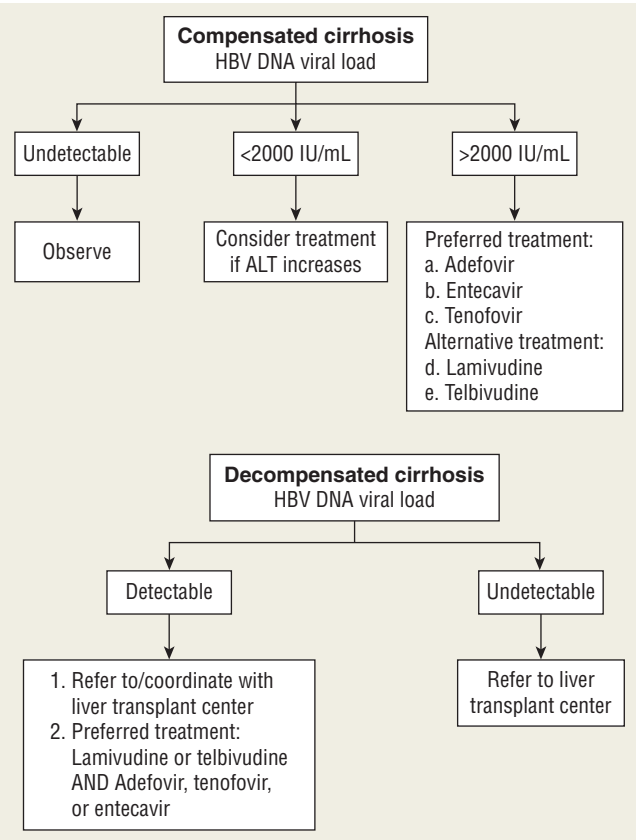

FIGURE 47-2. Suggested treatment algorithm based on the recommendations of the American Association for the Study of Liver Diseases for chronic hepatitis B virus-infected patients with cirrhosis. *(Adapted from reference 27.)*

Patients who respond to interferon therapy tend to have a more durable response than that seen with lamivudine, likely as a consequence of interferon's stimulation of the immune response for seroconversion. Seroconversion rates range from 30% to 40% and are often permanent, although relapse is more likely in HBeAg-negative patients.[35,42] The duration of therapy is finite, although the optimal duration of treatment is unclear. Treatment for a minimum of 12 months is associated with greater sustained virologic response rates than treatment for 4 to 6 months. Seroconversion can occur during or after therapy is complete. An extended treatment duration of 24 months may benefit the difficult-to-treat HBeAg-negative patient.[35] Additional benefits of interferon-based therapy in responsive patients is a reduction in cirrhosis, HCC, and death.[27] Conventional interferon therapy is plagued with numerous problems, including the inconvenience of thrice-weekly injections; however, standard interferon therapy has virtually been replaced by the use of pegylated interferon (peg interferon) because of the benefits in ease of administration, decreased side effect profile, and improvements in efficacy. Compared with conventional interferon, peginterferon has a longer half-life enabling once-weekly injections. For HBV treatment, the approved peg-interferon formulation is pegIFN-α2a. Studies comparing pegIFN-α2a monotherapy with peginterferon-α2a–lamivudine combination therapies suggest that combination therapy caused greater HBV DNA suppression than peginterferon-α2a monotherapy; peginterferon-α2a monotherapy better achieved HBeAg seroconversion than lamivudine monotherapy with no difference in combination therapy; and combination therapy resulted in less lamivudine resistance than lamivudine monotherapy. Interferon-based therapies are still limited by multiple adverse effects (Table 47–9). The high risk of infection precludes use of interferon in decompensated cirrhotic patients.[27] In patients with compensated cirrhosis, interferon appears to be safe and effective, although it can provoke hepatic flares and precipitate hepatic decompensation.[27,35] The optimal role of interferon-based therapies in HBV treatment is not defined.

TABLE 47-9 Common Side Effects Associated with Peginterferon Therapy (Experienced by >20% of Patients)

Fatigue	Arthralgia
Fever	Musculoskeletal pain
Headache	Insomnia
Nausea	Depression

Lamivudine

Lamivudine, a nucleoside analog, has antiviral activity against both HIV and HBV. It is dosed at 100 mg daily in adults; the optimal duration of treatment is unknown. In both HBeAg-positive and -negative patients, lamivudine demonstrates profound viral suppression. HBV DNA serum levels are undetectable in 90% of lamivudine-treated patients after 4 weeks.[35] Normalization of ALT levels occurs gradually over 3 to 6 months in most patients. Additionally, fibrotic changes are reduced and may be reversed in some cases. Response to lamivudine is dependent on baseline ALT levels, with higher levels corresponding to greater likelihood of seroconversion. Seroconversion rates increase with duration of therapy and are at 50% by the fifth year of therapy.[27] The advantages of lamivudine-based therapy include its safety profile and patient tolerability and the convenience of an oral tablet. Moreover, lamivudine can safely be used in immunosuppressed and cirrhotic patients.[42] Patients who can maintain long-term viral suppression have reduced and possibly reversed cirrhotic changes. However, lamivudine therapy is not without problems. There is no clear duration of treatment and HBeAg-negative patients have a less than 20% viral suppression rate after 12 months of therapy. Serum HBV DNA levels return to baseline upon cessation of therapy.[43] Seroconversion rates are less than 20% after 1 year of therapy and will relapse in up to 58% of patients. Relapse rates are highest among Asian patients.[42] Resistance is inevitable and can undermine the value of treatment. The emergence of YMDD mutants increases with each subsequent year of therapy, with rates approaching 70% after 4 years of therapy, and is associated with returns of serum HBV DNA and elevated ALT levels.[21,23] Relapse is associated with reversion of histological benefits.[27] Although seroconversion can occur even after the appearance of resistant mutants,[23] the prognosis is poor for most patients who develop resistance.[35] In HBeAg-negative chronic hepatitis B, where therapy is long term and the exact duration of therapy unknown, resistance is an especially daunting problem.[27]

Patients on lamivudine therapy require monitoring for breakthrough infection. If patients have confirmed lamivudine-resistant mutations, therapy should be changed to include agents with activity against lamivudine-resistant HBV.[27]

Adefovir

Adefovir dipivoxil is an acyclic nucleotide analog of adenosine monophosphate. The drug acts by inhibiting HBV DNA polymerase. It is dosed at 10 mg daily for 1 year in adults, although the optimal duration of therapy is unknown.[27] A 48-week course of treatment is effective in improving histologic findings, reducing serum HBV DNA and ALT levels, and increasing HBeAg seroconversion in both HBeAg-negative and -positive patients.[44,45] The durability of the response is likely related to a long duration of treatment following seroconversion.[46] Further suppression of HBV DNA and ALT levels occurred in long-term therapy over 4 to 5 years with improved histologic findings.[38] In HBeAg-negative patients treated for 48 weeks, the benefits of therapy were lost within 4 weeks of stopping adefovir. In contrast, patients treated for 144 weeks maintained benefits throughout the treatment duration and saw continued improvement in fibrosis as the therapy continued. However, rates of seroconversion were low.[38] Historically, increases in serum creatinine limited treatment to doses of 30 mg/day or less. In patients treated chronically at a dose of 10 mg daily, the incidence of nephrotoxicity was the same as placebo. In patients treated with 10 mg/day for a subsequent 48 weeks, the incidence of serum creatinine abnormalities did not change from the first year of therapy.[38] Resistance to adefovir has not been seen within the first year of therapy. Resistant mutants have been identified and do respond to lamivudine therapy, although the full impact on clinical outcomes is not known.[27] In patients with developing lamivudine resistance as demonstrated by rising HBV DNA levels, the addition of adefovir was more effective if done while ALT levels were still normal.[47] The risk of adefovir resistance was higher among patients who were switched from lamivudine to adefovir rather than among those who had combination therapy of lamivudine and adefovir.[48] To prevent adefovir resistance, lamivudine should be continued even in patients with lamivudine-resistant HBV, although the optimal duration for combination therapy is not known.[27] The optimal drug therapy in adefovir resistance is not known.[27]

Entecavir

Entecavir is a guanosine nucleoside analog that acts by inhibiting HBV polymerase. An oral agent, it is more potent than lamivudine and adefovir in suppressing serum HBV DNA levels and is effective in lamivudine-resistant HBV.[27,49] Rates of HBeAg seroconversion are higher in patients with elevated baseline ALT.[27] The drug is dosed at 0.5 mg daily for adults with treatment-naive or non-lamivudine-resistant infections and at 1 mg daily in lamivudine-refractory patients. In a 48-week trial comparing it to lamivudine, entecavir resulted in significantly higher rates of histologic improvement, HBV DNA reduction and undetectability, and ALT normalization. No difference in HBeAg loss or seroconversion was observed in HBeAg-positive patients.[50] In HBeAg-negative patients, entecavir showed greater histologic, virologic, and biochemical responses compared with lamivudine.[51] Among all patients, no differences in fibrosis improvement were seen and resistance to entecavir was not detected after 2 years of therapy.[50,51] However, treatment response in lamivudine-resistant patients is lower overall and entecavir-resistant mutants can develop during the course of treatment.[27] Entecavir resistance is rare in nucleoside naïve patients; however resistance is most likely to occur in patients with preexisting lamivudine resistance and approaches 50% after 5 years of entecavir therapy in lamivudine refractory patients.[47,52] Patients on lamivudine who develop resistance and are switched to entecavir should stop lamivudine therapy.[27] Recent data suggest resistance to both lamivudine and adefovir is a risk factor for entecavir resistance.[53] In terms of safety, entecavir is comparable to lamivudine. Patients switched from lamivudine to entecavir are at risk for hepatic flares, although severe flares are unlikely.[49]

Telbivudine

Telbivudine is a HBV-specific nucleoside analog that acts as a competitive inhibitor of viral reverse transcriptase and DNA polymerase. The drug inhibits HBV DNA synthesis with no activity against other viruses or human polymerases.[37] Compared with lamivudine, telbivudine is a more potent suppressor of HBV DNA with greater median HBV DNA log reductions and more patients achieving undetectable viral loads.[37,49,54] More patients also experienced a normalization of ALT levels. Although more telbivudine-treated patients experienced seroconversion, the difference was not significant even at 2 years of therapy. Treatment failure, including an inability to suppress HBV DNA levels below

5 log, occurred statistically more often in lamivudine treated patients than in telbivudine treated ones.[54] Compared with adefovir, telbivudine significantly reduced HBV DNA levels, although no difference was seen for HBeAg loss or ALT normalization.[52] Resistance may limit telbivudine's efficacy, although long-term data are needed.[49] Telbivudine selects for the YMDD mutations. During a 2-year evaluation, resistance increased substantially from year 1 at 5% to 25.1% in year 2 in HBeAg-positive patients and from 2.3% to 10.8% in HBeAg-negative patients.[54,55] In comparison, lamivudine resistance increased from 11% to 39.5% among HBeAg-positive patients and from 10.7% to 25.9% in HBeAg-negative patients.[54,55] Varying degrees of hepatic impairment do not alter the kinetics of the drug, nor does the coadministration of lamivudine or adefovir.[56,57] Combination therapy of telbivudine and lamivudine did demonstrate greater seroconversion rates but the difference was not statistically different from monotherapy.[58] Telbivudine monotherapy is comparable with lamivudine in safety with few case reports of myopathy and elevations of creatinine kinase.[54,55]

Tenofovir

Tenofovir is a nucleotide analog first approved for use in HIV and approved for HBV in 2008. It is available either as a single agent oral tablet or as a combination therapy with emtricitabine. Tenofovir is similar to adefovir but without the nephrotoxicity seen with adefovir, permitting adult dosing to be 300 mg versus 10 mg of adefovir. The higher dosing strategy likely confers several advantages to tenofovir in comparison with adefovir. Among HBeAg-positive patients, more patients treated with tenofovir had undetectable HBV DNA, ALT normalization, and loss of HBsAg than the adefovir-treated group. Rates of histologic response and seroconversion were similar. Among HBeAg-negative patients, more patients treated with tenofovir had undetectable HBV DNA, but there was no difference in ALT normalization, histologic response, and no patients lost HBsAg.[59] In lamivudine-resistant chronic hepatitis B, tenofovir showed an earlier and greater suppression of HBV DNA than adefovir. There are limited data on tenofovir resistance. Tenofovir can overcome adefovir treatment failure but adefovir mutants persist, suggesting cross-resistance.[60] The long-term impact of tenofovir resistance or optimal management to prevent resistance is unknown at this time. Toxicity is minimal compared with adefovir. [42]

ALTERNATIVE DRUG TREATMENTS

Emtricitabine is a cytosine analog approved for use in HIV and with activity against HBV. It is currently not approved for HBV but has been used in combination with tenofovir. In a comparative study with placebo, emtricitabine showed a significant decrease in viral load to undetectable in 54% of patients, normalization of ALT levels in 65% of patients, and improvement in necroinflammatory score. However, seroconversion to anti-HBeAg and HBeAg loss did not differ between placebo and emtricitabine. Emtricitabine safety was comparable to placebo. At the end of the 48-week treatment, 20 emtricitabine-treated patients had YMDD or YMDD-related resistance mutations.[61] Emtricitabine is similar to lamivudine and thus likely to induce similar mutations.[27]

Combination therapy has been proposed to increase drug effectiveness and to counter the issues of resistance. Potential disadvantages for combination therapy include costs, toxicity, and drug interactions. Currently no data exist that combination therapy improves effectiveness. Data for preventing resistance is mixed as complete suppression of resistance has not been achieved with combination therapy. Combination therapy with interferon and lamivudine creates less resistance than lamivudine monotherapy, but the combination did not change the post-therapy viral response in comparison to interferon monotherapy.[27] YMDD mutants remain susceptible to adefovir.[47] Adding adefovir to patients on lamivudine when HBV DNA levels began to increase better maintained normal ALT levels and suppressed HBV DNA than waiting to add adefovir until after ALT levels increased.[46] Adding adefovir to lamivudine when lamivudine resistance develops in HBeAg-negative patients was associated with improved ALT normalization and a lower likelihood for virological breakthrough or development of adefovir resistance. Both groups had similar rates of virologic response.[48] In a comparison study of lamivudine monotherapy versus lamivudine-adefovir combination therapy in treatment-naïve patients, similar rates of seroconversion, HBV DNA suppression, and rates of ALT normalization were observed. There was a lower rate of YMDD mutation resistance in the combination therapy group at 15% versus 43% in the lamivudine monotherapy group.[62] A comparison study of telbivudine, lamivudine, or a combination of telbivudine and lamivudine did not find any benefit to combination therapy as compared with telbivudine monotherapy. Resistance was not reported.[63] The American Association for the Study of Liver Disease recommends combination therapy with lamivudine or telbivudine plus adefovir, tenofovir, or entecavir for decompensated cirrhotic patients with chronic HBV regardless of HBV DNA levels or HBeAg status.[27] Moreover, current guidelines suggest combination therapy with two or more agents in patients who develop antiviral resistant HBV.[27]

SPECIAL POPULATIONS

The decision to treat cirrhotic patients depends on disease progression. Patients with decompensated cirrhosis require referral for liver transplant. Most recently updated guidelines suggest lamivudine, telbivudine, adefovir, tenofovir, and entecavir are possible agents for use in cirrhotic patients (see Fig. 47–2).[27]

In patients co-infected with HCV, the clinical practice is to treat the more dominant form of the hepatitis virus. There are no current recommendations on management of HBV/HCV co-infection. Previously published recommendations suggested treating HCV according to published guidelines and to consider the addition of entecavir or adefovir if HBV DNA levels remained stable or rose.[27]

Patients co-infected with hepatitis D, which requires infection with hepatitis B, may be treated with high-dose interferon alfa or peginterferon.[27] There is an overall paucity of data on HBV-HDV co-infection treatment. Lamivudine has not been shown to be effective, neither has ribavirin, a drug used in combination therapy with interferon for HCV treatment.[64,65]

In HIV coinfected patients, therapy should be tailored specifically to the patient. If the patient is being treated for HIV, certain regimens may be optimized to include drugs with efficacy against HBV, including tenofovir, emtricitabine, or lamivudine. If patients are on a stable regimen that does not include HBV-active drugs or are not considered for highly active anti-retroviral therapy (HAART), peginterferon-α or adefovir may be used.[27] Because of neutropenia associated with peginterferon-α, patients considered for interferon therapy should have CD4 counts >500 cells/uL. In patients being considered for HAART, combination therapy is recommended for HBV with either tenofovir and lamivudine or tenofovir and emtricitabine. Patients with confirmed lamivudine resistance should have tenofovir added to their regimens.[27]

Although the majority of chronic HBV patients are adults, children may be treated. Lamivudine is indicated for children age 2 years and older and interferon is approved for use in children age 1 year and older. Entecavir is approved for adolescents age 16 years and older, whereas pegylated interferon and adefovir do not have indications for pediatric dosing.

PHARMACOECONOMIC CONSIDERATIONS

Cost considerations in HBV include the cost-effectiveness of the HBV vaccine and available antiviral treatments. The use of a combined HAV/HBV vaccine is cost-effective.[17] Routine use of the HBV vaccine in HIV counseling and testing sites, including sexually transmitted disease clinics, showed it to be an effective and cost-effective measure in preventing HBV among high-risk groups. The model, which considered four different strategies in vaccination, including no vaccination, found that routine vaccination would cost $4,400 per QALY and per life-year saved. When costs of HBV treatment and transplants were included, the cost decreased to $2,200 per QALY, further supporting routine vaccination as a cost-effective measure.[58]

The cost-effectiveness of therapy for chronic HBV patients must address the approval of new agents for treatment. For noncirrhotic chronic HBV patients with elevated ALT levels, the most cost-effective therapy consisted of initiating treatment with lamivudine and switching to adefovir with the development of lamivudine resistance. The salvage strategy cost $8,447 per QALY. Pegylated interferon was not compared.[66] In chronic HBV patients with cirrhosis, entecavir was the most effective, yet more expensive option. Entecavir cost $25,626 per QALY as compared with adefovir's $19,731 per QALY. Salvage therapy was not found to be cost-effective in this patient population.[67] Pegylated interferon was not compared for initial treatment because of its relative novelty in HBV treatment; because interferon is not considered a treatment option for cirrhosis, it was not included in the analysis of cirrhotic patients.

CLINICAL CONTROVERSY

Although previously published guidelines do not support the use of IFN in cirrhosis because of the potential for an IFN-induced hepatic flare progressing to decompensation, some experts suggest peg-IFN-α2a may be an option for some patients with compensated cirrhosis. Moreover, some experts argue that lamivudine, although indicated for use in cirrhosis, may cause clinical decompensation because of the drug's high risk for resistance and, hence, viral rebound triggering decompensation.

HEPATITIS C

HCV is approximately 5 times as common as HIV and is responsible for an estimated 10,000 chronic liver disease-associated deaths per year.[1] More than 190,000 deaths from HCV-related disease are expected between 2010 and 2019, with projected costs exceeding $10 billion.[68] Most acute infections are asymptomatic and the course of the infection is insidious. As a result, many patients are not diagnosed until significant disease progression.

EPIDEMIOLOGY

8 HCV is the most common blood-borne pathogen. In the United States, approximately 3.2 million people are chronically infected with HCV.[1] An estimated 17,000 new HCV infections occurred in 2007; however, because of the clinically silent nature of acute infections and the 20- to 30-year disease progression to cirrhosis, it is the 200,000 patients infected per year in the late 1980s who contribute to today's HCV burden.[68] Considering that HCV infection is prevalent in high-risk populations such as prisoners, IDUs, and the homeless, and that this population is generally excluded from most surveys, the actual number of chronically infected people is significantly higher. Nearly 75% of infected people may not be identified.[68] The single largest risk factor for infection is injection drug use. Some experts also consider other illicit drug use, for example intranasal cocaine, as a risk factor because of the possible contamination of drug paraphernalia not limited to syringes and needles.[4] Historically, blood transfusion posed a major risk for infection. Patients who received blood transfusions or transplants before 1992, clotting factors before 1987, or were ever on chronic hemodialysis represent a majority of chronic HCV infections.[1] Improved screening of blood in 1992 decreased the risk of transfusion-related HCV.[70] Currently hemodialysis and transfusions both represent less than 1% of risk factors in known HCV exposures.[4] Healthcare associated transmission is rare; however, a much publicized outbreak linked to an endoscopy center in Nevada in 2007 prompted an examination of HCV outbreaks associated with healthcare. Since 1998, over 58,000 patients have been screened for possible exposure to HCV in non-hospital healthcare venues, including the Nevada incident. The identified risk in Nevada was unsafe injection practices.[1] Although sexual transmission is an often-identified risk factor, the actual risk is very low and may be confounded by other behaviors. Studies of monogamous couples in long-term relationships do not support the use of barrier methods for preventing transmission. Testing of sexual partners in a monogamous relationship is mainly recommended for ease of mind.[70] Although sexual contact is considered an inefficient means of HCV transmission, multiple sexual partners and co-infection with sexually transmitted diseases, including HIV, increase the risk for HCV sexual transmission.[71]

Screening

Although acute HCV infections are often not recognized and many progress to chronic infections, routine screening for infection is not recommended. Various guidelines and position papers for the screening and treatment of chronic HCV infection exist. Screening is warranted in patients who are at high risk for infection (Table 47–10). Although the risk of HCV in monogamous relationships is very low and barrier methods are not recommended, sexual partners are recommended to be tested for the sake of reassurance.[70] The risk of infection from other needle-borne exposures, such as acupuncture, tattooing, and body piercing, is unclear and at this time not an indication for routine screening for HCV.[70]

ETIOLOGY

HCV is a single-stranded RNA virus of the family *Flaviviridae* notable for lacking a proofreading polymerase and enabling frequent viral mutations.[68,72] The virus replicates within hepatocytes and like hepatitis B, is not directly cytopathic. HCV replicates copiously

TABLE 47-10 Recommendations for Hepatitis C Virus (HCV) Screening

Current or past use of injection drug use
Co-infection with HIV
Received blood transfusions or organ transplantations before 1992
Received clotting factors before 1987
Patients who have ever been on hemodialysis
Patients with unexplained elevated ALT levels or evidence of liver disease
Healthcare and public safety workers after a needlestick or mucosal exposure to HCV-positive blood
Children born to HCV-positive mothers
Sexual partners of HCV-positive patients

ALT, alanine transaminase; HIV, human immunodeficiency virus.
Data from Hoofnagle.[72]

From Hoofnagle.[72]

with an estimated serum half-life of 2 to 3 hours. The result is a proliferate, persistently mutating virus posing an immense challenge for immune-mediated control.[72]

HCV is differentiated into six major genotypes, numbered 1 to 6, and varying in nucleotide sequence by 30% to 50%. Genotypes are further classified into subtypes (a, b, c, etc.), which differ by 10% to 30% in nucleotide sequence. The most widely distributed genotypes are 1 and 2, with genotype 1 the most common (Table 47–11). In the United States, the majority of infections are caused by genotypes 1a and 1b, followed by genotypes 2 and 3. Although infection caused by any of the genotypes can lead to cirrhosis, end-stage liver disease (ESLD), or HCC, the significance of the infecting genotype is related to therapeutic response. Genotypes 2 and 3 are at least twice as likely to respond to therapy as genotype 1. Genotypes 4, 5, and 6 are not well understood but are expected to respond with rates similar to genotype 1.[72]

PATHOPHYSIOLOGY

In the vast majority of cases, an acute HCV infection leads to chronic infection. The immune response in an acute HCV infection is mostly insufficient to eradicate the virus. During the early phases of infection, natural killer cells are activated as HCV RNA levels rapidly rise. A combined effort of HCV specific CD4 and CD8 T lymphocytes and interferon co-expression decrease viral replication. The eradication of HCV by cytotoxic T lymphocytes may occur either as a result of induced apoptosis by infected hepatocytes or by the release of interferon to stifle viral replication. The extent of hepatocyte apoptosis may correlate with the course of the disease. Liver damage and HCC are associated with high levels of hepatocyte apoptosis. Low levels of apoptosis are associated with viral persistence. Moreover, CD4 T-helper cells are unlikely to mediate liver injury, but rather may promote an environment conducive for other immune responses damaging to the liver. Bystander killing may also play a role in hepatic damage. Although HCV infects less than 10% of hepatocytes, up to 20% of cells are activated for apoptosis.[64]

HCV poses a daunting challenge for immune control because of its rapid viral diversification. HCV genomic mutations are detectable within 1 year of infection. Resolved cases of HCV are defined by a vigorous T-cell response with highly active CD8 and persistent CD4 cell response. It is hypothesized that the CD8 activity mediates protective immunity but requires the aid of CD4 cells to maintain the response during viral mutations.[64]

CLINICAL PRESENTATION

In an acute HCV infection, most patients are asymptomatic and undiagnosed. HCV RNA is detectable within 1 to 2 weeks of exposure and levels rise quickly during the initial weeks. The HCV RNA levels plateau at 10^5 to 10^7 international units/mL and precede a peak in ALT levels and the onset of symptoms. Rising ALT levels indicate hepatic injury and cell necrosis. It is not unusual for levels to exceed values 10 times the upper limits of normal.[72] Although HCV RNA serum levels can show interpatient variability, the levels tend to be stable for the individual patient.[65] Typically, symptoms occur 7 weeks after the infection, with a range of 3 to 12 weeks. Approximately one third of adults will experience some mild and nonspecific symptoms, including fatigue, anorexia, weakness, jaundice, abdominal pain, or dark urine.[68,72] Acute infections rarely progress to fulminant hepatitis, although the course can be severe and prolonged. If the infection is self-limiting, symptoms last several weeks as ALT and HCV RNA levels subside. Almost all patients, including immunosuppressed patients, will develop antibodies to HCV. Typically, antibodies are not detectable until either at the time of or shortly after the development of symptoms and are not used diagnostically in an acute infection because a third of infected patients may test negative at the onset of symptoms despite infection.[72]

Up to 85% of acutely infected patients will go on to develop a chronic HCV infection, defined as persistently detectable HCV RNA for 6 months or more. HCV RNA levels and ALT levels can fluctuate and even have periods of undetectable HCV RNA and normal ALTs. Most patients will have few, if any symptoms. The most common symptom is persistent fatigue. Additional symptoms include right upper quadrant pain, nausea, or poor appetite. On physical examination, hepatomegaly is usually present. With advanced disease, stigmata of liver disease is evident, such as spider nevi, splenomegaly, palmar erythema, testicular atrophy, and caput medusae. However, almost all patients with chronic HCV will have some degree of necroinflammatory disease on liver biopsy. The extent of structural damage varies considerably.[72] Chronic inflammation of the liver from chronic HCV infection may result in fibrosis. Fibrosis is defined by altered hepatic perfusion creating a distorted structure and affecting normal function.[75] The speed of fibrosis progression can vary and is not necessarily predicative of cirrhosis development. An estimated 20% of chronic HCV patients will develop cirrhosis and half of those patients will progress to either decompensated cirrhosis or HCC. Historically, one third of untreated patients may expect to develop cirrhosis within 20 years, while another third of patients may delay the onset of cirrhosis for 50 years or never develop it.

It is currently not possible to definitively identify patients at risk for disease progression.[75] Several factors may correlate with a decreased risk for chronicity. Being younger than 40 years old, female, non-black, not immunosuppressed, and with a symptomatic acute HCV infection decreases the risk of developing a chronic infection. Being older than age 20 years at infection triples the risk for chronic HCV. Blacks, especially black men, are more likely to develop chronic infection and have lower treatment responses.[76] Becoming symptomatic and having jaundice is associated with a lower likelihood of chronic infection, perhaps correlating to a stronger immune response to the acute infection. Finally, immunosuppressed patients, such as those with HIV, are more prone to chronic infection although they are not inherently unable to clear the infection.[72] Recently a variation on a gene encoding for endogenous interferon has been described which is associated with a difference in response to treatment and may explain differences in response between patients of African American and European ancestry.[77] Similarly, disease progression is associated with increased age, male sex, continued alcohol intake, obesity, and HIV coinfection. Diabetes, as well as steatosis, may also potentiate fibrosis progression. Viral load and genotypes other than genotype 3 are not factors. Genotype 3 may be associated with fibrosis progression.[75] The development of HCV cirrhosis poses a 30% risk over 10 years for the development of ESLD, as well as a 1% to 2% risk per year of developing HCC.[70] Progression to cirrhosis is the primary concern in patients infected with HCV for 2 decades or longer. Unfortunately, because acute infections are typically not recognized, the diagnosis of HCV is often not made until disease progression.

HCV is also rarely associated with extrahepatic manifestations. The most common is cryoglobulinemia, a local deposition of immune complexes that cause vasculitis. Typical manifestations involve the skin and internal organ damage, predominantly affecting the kidneys. Symptoms of cryoglobulinemia include fatigue, skin rash, purpura, arthralgias, renal disease, and neuropathy.[72] Other, more rare symptoms include B-cell non-Hodgkin lymphoma, Sjögren syndrome, glomerulonephritis, arthritis, corneal ulcers, thyroid disease, neuropathies, and porphyria cutanea tarda.[78]

For many patients, a diagnosis of hepatitis C is incidental. Some patients are diagnosed after finding persistently abnormal transaminases. Unfortunately, those patients who present with symptoms typically have advanced disease. A diagnosis of chronic HCV is confirmed with a reactive enzyme immunoassay for anti-HCV. Testing for anti-HCV is not routinely recommended because of the low prevalence of HCV in the general population and the nonspecificity of the test. Although many professional associations advocate testing for both symptomatic and asymptomatic persons with risk factors for HCV, the U.S. Preventative Task Force does not recommend routine screening of high-risk individuals.[79]

TREATMENT

Hepatitis C Virus

DESIRED OUTCOME

The primary goal of therapy is to eradicate HCV infection. Resolving the infection prevents the development of chronic HCV infection sequelae including death. Even patients who are unable to achieve cure may see histological improvements with therapy.[69]

GENERAL APPROACH TO TREATMENT

Treatment for HCV is necessary because nearly 85% of acutely infected patients develop chronic infections and are at risk of developing cirrhosis, ESLD, and HCC. Moreover, HCV infection is the most common indication for liver transplant. Treatment is indicated for patients previously untreated who have chronic HCV, circulating HCV RNA, increased ALT levels, evidence on biopsy of moderate to severe hepatic grade and stage, and compensated liver disease.[69] According to the American Association for the Study of Liver Diseases, among chronic HCV patients, symptomatic cryoglobulinemia is an indication for HCV antiviral therapy irrespective of the stage of liver disease.[70] Therapy is not without risk, and in some cases may not be recommended, such as in patients with decompensated liver disease, a history of severe uncontrolled psychiatric disorder, and in patients with severe hematologic cytopenias.[69] Table 47–12 lists the contraindications to therapy.

Before therapy is initiated, quantitative HCV testing, genotyping, and a liver biopsy are performed. Quantitative amplification assays for HCV RNA are performed in patients who are candidates for therapy to obtain baseline information on the viral load. A baseline HCV RNA level serves as a prognostic indicator for response and is used to monitor virologic response once therapy is initiated. Genotyping is also necessary for treatment candidates because response to therapy and duration of therapy vary depending on the infecting genotype. Liver biopsy is used to determine histologic grade and stage and to guide therapy.[70] Because most chronic HCV patients are not diagnosed for years, a biopsy can provide clinical information on the extent of hepatic damage incurred since infection and offer baseline data to assess disease progression.[69] In some patients, liver biopsy may support a decision to delay treatment.

Overall, the greatest predictor of treatment response is infection with nongenotype 1. Adherence to therapy is a crucial component in response, especially among genotype 1-infected patients. Patients who take at least 80% of their medications for at least 80% of the treatment time are more likely to successfully respond to therapy.[80] Treatment response is monitored according to the following terminology:

Rapid virological response (RVR): a patient with undetectable viral load at week 4 of treatment

Early virological response (EVR): patient who experiences at least a 2-log reduction in viral load by the 12th week of treatment (partial EVR) or a patient with undetectable viral load by the 12th week of treatment (complete EVR)

End-of-treatment response (ETR): patient with no detectable viral load at the end of treatment

Sustained virological response (SVR): patient with no detectable viral load at the conclusion of therapy and 24 weeks later

Relapser: patient who responds to therapy but whose viral load becomes detectable at the conclusion of therapy

Nonresponder: patient with a detectable viral load after 24 weeks of therapy

Null responder: patient with a viral load that never decreased by >2 logs after 24 weeks of therapy

Partial responder: patient with at least a 2-log reduction in viral load but detectable viral levels after 24 weeks of therapy

Patients who achieve a RVR are highly likely to achieve cure; however, patients who do not achieve RVR should not be assumed to be nonresponsive. A negative RVR does not imply inability to achieve SVR, rather it indicates patients will require a full course of therapy and potentially an extended duration of therapy. Patients who experience a complete EVR are more likely to also have an SVR. Less than 3% of patients who fail to have an EVR can be expected to achieve an SVR.[69,70] Achieving a complete EVR is a better marker of SVR than achieving a partial EVR. If the goal of therapy is viral eradication and an EVR is not achieved, therapy may be discontinued at 12 weeks. In some patients, however, histologic benefits can occur without an EVR and histologic improvements alone may warrant continuation of therapy.[69]

TABLE 47-12 Contraindications to Hepatitis C Virus Combination Therapy

Autoimmune hepatitis
Decompensated liver disease
Pregnant or unwilling to comply with contraception
Patients with untreated thyroid disease
Patients with serum creatinine >1.5 mg/dL or on hemodialysis
Patients with major, uncontrolled depression
Patients with severe concurrent medical disease
Patients with solid organ transplant including renal, heart, or lung

NONPHARMACOLOGIC THERAPY

All chronic HCV patients should be vaccinated against hepatitides A and B. Lifestyle changes are an important factor in reducing health consequences in hepatitis C. Continued alcohol use is a known risk factor for disease progression and severity. There is no established lower limit of alcohol consumption at which disease progression is not seen. Obesity is also a factor and patients should be encouraged to eat a balanced diet and exercise regularly to maintain a normal weight. Progression of fibrotic changes is

TABLE 47-13 Recommended Hepatitis C Virus Treatment Dosing

Genotype	Peg-IFN Dose	Ribavirin Dose		Duration[a]
1, 4	Peginterferon-α2a 180 mcg/wk	≤75 kg[b]	1,000 mg	48 weeks
	or	>75 kg	1,200 mg	
	Peginterferon-α2b 1.5 mcg/wk	≤65 kg	800 mg	48 weeks
		>65–85 kg	1000 mg	
		>85–105 kg	1200 mg

	Peginterferon-α2b 1.5 mcg/wk		800 mg	24 weeks

[a] Actual treatment duration may be different depending on virological response.
[b] Patient weight.

associated with obesity. Moreover, obesity and decreased insulin resistance contribute to decreased response to interferon. Smoking may also contribute to disease progression. Patients should be encouraged to maintain good overall health, stop smoking, and avoid alcohol and illicit drugs.[70,81] The use of herbal therapy is ineffective.[40] Patients should consult with their physician prior to initiating any herbal therapies and minimize prescriptive drug use if possible.[70]

PHARMACOLOGIC THERAPY

9 The current standard of care for chronic HCV patients is a combination therapy of a once-weekly injection of peginterferon and a daily oral dose of ribavirin. Overall response rates are greatest with combination therapy at an SVR rate of 54% to 56%.[69] Therapy is optimized based on genotype, patient weight, and response to therapy. Table 46–13 lists current therapeutic regimens. For genotype 1, evaluation for RVR at 4 weeks is recommended as an indicator of the probability of achieving an SVR. Patients who do not achieve a RVR should be evaluated for virologic response at 12 weeks (EVR). Because therapy is not without a significant side-effect profile and because failure to achieve a complete EVR is so strongly correlated with treatment failure, some clinicians will terminate therapy early in genotype 1 patients (Fig. 47–3). Patients who achieve complete viral suppression between weeks 12 and 24 may be treated for as long as 72 weeks.[70] Conversely, because genotypes 2 and 3 respond so well to therapy, there are data to support early treatment termination in patients who show an EVR at 4 weeks (Fig. 47–3).[82] Current guidelines suggest patients with genotypes 2 and 3 be treated for the full 24 weeks of therapy.[70]

Interferon

Historically, treatment of HCV involved the use of interferon-α. Although interferon monotherapy resulted in an SVR in less than 10% of patients, the response was durable. The addition of a pegylated moiety to interferon improved the pharmacokinetic profile of the drug to reduce injection frequency from 3 times to once a week, and doubled SVR rates. Even among cirrhotic patients, peginterferon was safe and effective.[69] Two peginterferons are available, peginterferon-α2a (Pegasys) and peginterferon-α2b (PEG-Intron). Table 47–14 lists the differences between the two drugs. It is unclear which therapy is superior. Achievement of SVR may be more likely in patients with an early and intense viral suppression. The current guidelines do not address which formulation of interferon should be preferentially used in HCV treatment.

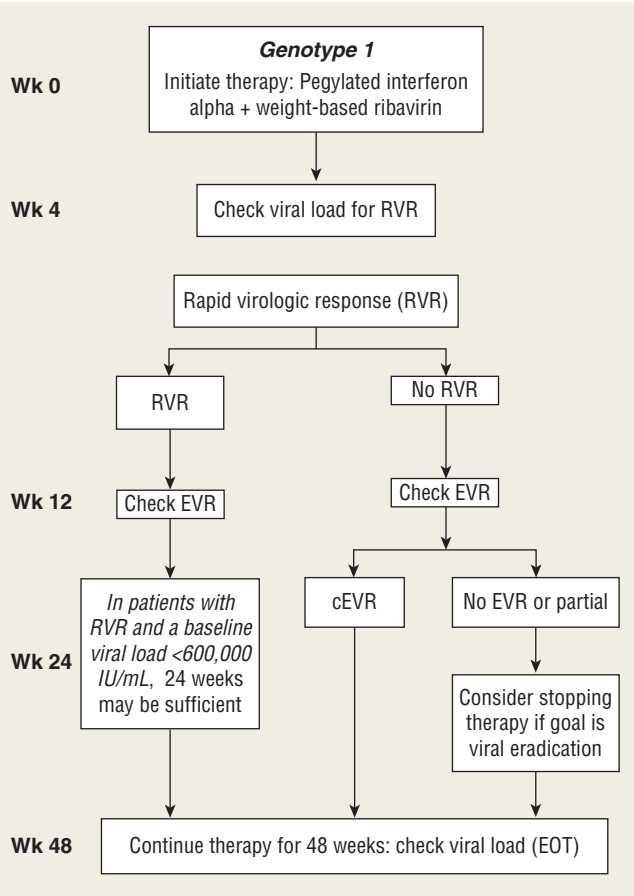

FIGURE 47-3. Suggested response-optimized chronic hepatitis C virus infection treatment regimens based on the recommendations of the American Association for the Study of Liver Diseases.[70] EOT, end of treatment. *(Adapted from reference 70.)*

Ribavirin

Ribavirin, a synthetic guanosine analog, is ineffective as a monotherapy for HCV and its exact mechanism of action is unknown. When added to interferon, ribavirin significantly increases SVR rates, especially among genotypes 2 and 3. Ribavirin is dosed based on weight for optimal response in genotype 1 and 4 infections. Although monotherapy with peginterferon is an option for patients with contraindications to ribavirin, ribavirin is ineffective as monotherapy and should not be used alone. However, SVR rates are highest among patients treated with a combination of peginterferon and ribavirin at >40% for genotype 1 patients and at approximately 80% for genotypes 2 and 3.[69]

TABLE 47-14 Pegylated Interferon Comparison

	Pegasys	PEG-Intron
Interferon	Alfa-2a	Alfa-2b
Indications	HBV, HCV	HCV
PEG moiety (weight)	Branched (40 kDa)	Linear (12 kDa)
Distribution	8–12 L; highest concentration in liver, spleen, kidneys	Body-weight dependent: 1 L/kg; distributes throughout body
Metabolism	Liver	Liver
Excretion	Renal	Renal
Dosing	Fixed: 180 mcg/wk subcutaneously	Weight dependent: 1.5 mcg/kg/wk subcutaneously

HBV, hepatitis B virus; HCV, hepatitis C virus.

⑩ Side effects of therapy are extensive and a major obstacle to successful patient completion of therapy (see Table 47–9). Although many patients require dose reductions for laboratory abnormalities, very few result in withdrawal of therapy. In contrast, more patients prematurely stop therapy because of adverse events such as fatigue or flu-like symptoms.[84] The most common laboratory abnormalities are neutropenia, thrombocytopenia, and anemia. Ribavirin-induced hemolytic anemia is an inevitable effect of therapy, although varying in severity among patients. Anemia results from ribavirin uptake into erythrocytes, inducing membrane damage and resulting in hemolysis. Patients may complain of fatigue as hemoglobin levels decrease even though dose reductions are not recommended until hemoglobin levels fall to 10 g/dL. The mean decrease in hemoglobin is 3 g/dL in the initial weeks of therapy; thereafter, levels stabilize until discontinuation of therapy. Hemoglobin levels normalize once ribavirin is stopped.[84] Interferon can cause bone marrow suppression, resulting in neutropenia and thrombocytopenia. Pegylated interferons are more likely to cause neutropenia than non-peginterferon. Dose reductions are recommended for neutrophil counts <750 cells/mm; discontinuation is recommended at <500 cells/mm. However, patients are not at a greater risk for infection. Neither nadir neutrophil counts nor total neutrophil decrease from baseline are related to infection. One study examined the risk for total, viral, fungal, and bacterial infections and concluded that neither dose reductions of interferon nor the addition of granulocyte-stimulating factor in HCV-treatment-induced neutropenia is warranted.[85]

Up to one third of patients are expected to experience some degree of depression during treatment, partly because of interferon's interference with the serotonin pathways.[70] Although many patients can be managed with selective serotonin reuptake inhibitors, various degrees of counseling and psychiatric consultations may be necessary. Severe depression and suicidal behaviors are rare but not undocumented. More common side effects include flu-like symptoms, which can be managed by acetaminophen or nonsteroidal inflammatory drugs.[69]

Alternative Treatments

Currently, investigated drug treatments for chronic HCV include taribavirin, various formulations of interferon, protease inhibitors, and polymerase inhibitors. Taribavirin is a ribavirin prodrug designed to concentrate within the liver with the goal of minimizing ribavirin-induced anemia. Longer acting versions of interferon, such as albuferon, are also being investigated. Telapravir, previously referred to as VX-950, is a reversible, selective, and specific HCV RNA protease inhibitor. It is an oral drug and current data suggest optimal dosing to be three times per day. Although telapravir demonstrated great viral load reduction even among previous interferon nonresponders, when taken alone it demonstrated viral breakthrough within 2 weeks of initiation.[86] Boceprevir is also a serine protease inhibitor currently being investigated in nonresponders. Early studies demonstrated profound viral suppression; however, the role of these agents will likely be as adjuncts to current therapy. Several other protease inhibitors are in various stages of development. A number of polymerase inhibitors are also in various stages of investigation. Studies in treatment-naïve and treatment-refractory patients are ongoing.[87]

Special Populations

Clinical trials are conducted with a patient population that generally does not reflect the patient spectrum encountered in clinical practice. There are no contraindications to the treatment of injection drug users, prisoners, persons with substance abuse issues, or persons with psychiatric disorders. However, barriers exist that can prevent access to care. A multidisciplinary approach to HCV treatment that includes mental health and substance abuse professionals should be considered in providing care to special populations.[88]

Published recommendations for treatment in various populations are as follows.[70]

Patients with Normal ALTs The decision to treat patients with normal ALTs is somewhat controversial and made on an individual patient basis. Clinicians should consider the risks and benefits of therapy, including histologic data, genotype, likelihood for response, and other factors, such as patient willingness to undergo therapy. Successful treatment significantly improves patient quality of life and reduces fatigue.[88] Moreover, the definition of normal can vary by reporting laboratory.

Patients with Decompensated Cirrhosis Patients with evidence of decompensation are candidates for liver transplantation. Therapy is generally not recommended unless administered by experienced clinicians. Serious adverse events including neutropenia and anemia are more likely in cirrhotics and may be managed through the use of growth factors.

Relapsed Patients The decision to retreat should consider the previous therapeutic regimen. Patients with prior treatment with interferon monotherapy or interferon and ribavirin should be considered for retreatment with peginterferon and ribavirin. The likelihood for SVR is lower, but may be as high as 50%. Retreatment with peginterferon and ribavirin after a previously failed course of peginterferon and ribavirin is not recommended.

Nonresponders Retreatment with peginterferon and ribavirin can increase SVR rates in patients previously treated with interferon monotherapy or interferon and ribavirin. Previous adherence, treatment tolerance, severity of underlying liver disease, as well as factors affecting treatment response, such as genotype, should be considered before deciding to retreat.

Accidental Needle-Stick Exposures Prophylactic treatment immediately following an accidental needle-stick exposure is not recommended for multiple reasons. Risk of transmission is considered low and among those infected, a percentage will successfully seroconvert and not require treatment. Because an initial delay in therapy does not increase the risk for developing a chronic infection, most experts wait 8 to 12 weeks before initiating treatment to allow for spontaneous remission. No formal guidelines exist as the optimal duration of treatment is unknown. Treatment is suggested for 12 to 24 weeks.

Injection Drug Users Injection drug use is a major factor in the cycle of HCV transmission. There are no recommendations against treatment for active IDUs although ongoing drug abuse can create many complications and expert opinion dictates that the decision to treat be made on a case-by-case basis. Treatment is recommended for recovering drug users, including those in drug treatment programs assuming patients are willing to comply with close monitoring and contraception requirements. Reinfection rates are low among injection drug users who achieve SVR.[89] It is recommended that patients continue ongoing drug abuse and psychiatric counseling while on HCV therapy.

Alcoholism Because continued alcohol use affects disease progression and severity and thus response to therapy, the cessation of alcohol use during therapy is recommended. Moreover, a period of abstinence before initiation of therapy is also recommended.

End-Stage Renal Disease The role of chronic HCV treatment is not defined for patients with end-stage renal disease. Hemodialysis is a risk factor for acquiring HCV infection yet a contraindication for ribavirin use. Patients with mild renal insufficiency (GFR ≥60 mL/min) may be treated with combination peginterferon and ribavirin. Monotherapy with interferon is an option in patients with

renal insufficiency or with end-stage renal disease as ribavirin is contraindicated in these patients due to risks of ribavirin accumulation and severe hemolytic anemia. Peginterferon can pose toxicity problems and requires careful monitoring.

HIV Co-Infection A large portion of HIV-infected patients who acquired the virus via injection drug use will be coinfected with HCV. Treatment poses additional problems because of hepatotoxicity issues associated with highly active antiretroviral treatment, hepatic complications from HIV-associated diseases, as well as flares in hepatitis as CD4 counts recover. Current guidelines recommend a 48-week course of therapy regardless of genotype. The prognosis for an SVR is worse than in patients infected with HCV only. In general, treatment is recommended and both HIV and HCV therapies can be coadministered with the exception of didanosine and zidovudine. The combination of ribavirin and didanosine can result in fatal lactic acidosis. Ribavirin causes hemolytic anemia and when combined with zidovudine can result in severe anemia.[91]

Children Currently therapy is indicated for children age 2 years and older and consists of peginterferon-α2b dosed at 60 mcg/m^2 weekly in combination with ribavirin 15 mg/kg daily for 48 weeks. Ribavirin is available in a liquid formulation. Pediatric patients tend to better tolerate therapy than adults. Pediatric patients should be evaluated as candidates for therapy similarly to the criteria for adults (Table 47–12).

African Americans Response rates of African Americans to HCV therapy is lower than rates observed with Caucasians and non-Hispanic whites, and genetic mutations of HCV may partially explain the discrepancies. African Americans have higher rates of chronic HCV than non-Hispanic whites and Hispanics and have greater rates of baseline neutropenia. African Americans with HCV should be evaluated for treatment and treated according to current guidelines. Baseline neutropenia (ANC <1500 mm^3) should not exclude patients from treatment.

PREVENTION

No vaccine is available for HCV. It is unlikely that a vaccine will be developed in the near future because of the mutagenesis of the virus. Patients infected with HCV should be counseled on not being blood, organ, or semen donors. Although the likelihood of household transmission is small, patients should minimize risks by avoiding possible blood or mucus exposure, such as not sharing razors or toothbrushes and covering open wounds. Patients who continue to use illegal drugs should avoid sharing all drug paraphernalia, as risk of transmission is not limited to needles and syringes.

PHARMACOECONOMIC CONSIDERATIONS

The progression of HCV-induced liver disease is highly variable and identifying which patients will progress remains a clinical challenge. Because not all patients will develop clinical sequelae, therapy may not be necessary in all patients. Given the relative unreliability of treatment to achieve an SVR, the costs associated with therapy, and the side-effect profile of the drugs, the cost-effectiveness of therapy may be questioned. Several studies have assessed the economic values of treating chronically infected HCV patients.

Issues of cost-effectiveness must weigh the public health impact of HCV against the costs of therapy. Despite the decreased incidence of acute HCV infections, epidemiologic data suggest the greatest disease burden will occur in 2015, reflecting the slow progression of disease in patients infected in the late 1970s and early 1980s. At the same time, HCV-related mortality is expected to triple.[92] A projected 720,000 patient-years will be lost as a result of decompensated cirrhosis and HCC. Predicted costs exceed $21 billion from the development of clinical sequelae. In patients who are younger than age 65 years, the costs associated with premature death are even higher—an expected $54 billion.[68] Although not all patients will develop HCV-related liver disease, it is not currently possible to identify which patients will have disease progression. Moreover, HCV-infected patients are prone to high levels of fatigue and neuropsychiatric and cognitive impairment, further contributing to decreased patient quality of life.[92]

Treatment with peginterferon therapy compared with traditional interferon is a cost-effective approach among noncirrhotic patients who are infected with any of the genotypes, especially in patients who are infected with nongenotype 1.[93] A review of studies published on the cost-effectiveness of therapies for HCV found that HCV therapy is cost-effective most of the time. Reduced cost-effectiveness was seen in patients treated with normal transaminases and healthy biopsies. However, most clinicians would opt not to treat such patients. Moreover, evaluating virologic response by week 12 and terminating therapy if no response is evident substantially lowers treatment costs by more than $15,000. Overall, various studies found that HCV treatment falls within the accepted cost-effectiveness margin, defined as less than $50,000 per QALY. The studies concluded that antiviral therapy costs offset costs associated with disease sequelae.[91]

CLINICAL CONTROVERSIES

In patients with advanced disease, a biopsy may be risky and offer no additional clinical information of whether to treat or not. Some clinicians believe that if therapy is to be initiated regardless, the liver biopsy offers no additional information. In patients with genotype 2 or 3, because response to therapy is so high and most clinicians treat despite biopsy results, there may not be a reason for biopsy.

Histologic improvement is not limited to patients who experience an SVR. Some clinicians believe interferon-based antiviral therapies, regardless of response, can decrease the incidence of HCC development.

Although ribavirin dosing is different for the treatment of genotype 1 depending on the formulation of pegylated interferon, most clinicians will dose ribavirin according to patient weight, irrespective of the formulation.

New data from clinical practice studies in Europe suggest peginterferon-α2a may achieve greater rates of SVR in genotype 1 patients. Data are in abstract form and contradict a recently published trial.

ABBREVIATIONS

AASLD: American Association for the Study of Liver Diseases
ALT: alanine aminotransferase
ANC: absolute neutrophil count
Anti-HAV: antibody to hepatitis A virus
CDC: Centers for Disease Control and Prevention
ESLD: end-stage liver disease

CHAPTER 48

Drug Therapy Individualization in Patients with Hepatic Disease and Genetic Alterations in Drug Metabolizing Activity

Y. W. FRANCIS LAM

KEY CONCEPTS

1. Hepatic elimination of drugs is primarily dependent on three variables: activity of metabolizing enzymes, plasma protein binding, and liver blood flow, each of which could be altered significantly in patients with liver diseases.
2. Hepatic extraction ratio represents a conceptual measure of the efficiency of extraction of drug from the blood by the liver, and is not a measure of the metabolic capacity of the liver per se.
3. Increased systemic bioavailability is primarily a concern for orally administered drugs that have a high hepatic extraction ratio.
4. Both phase I and II enzymes have been associated with altered drug exposure.
5. Evaluation of patient's liver function for assessment of need of dosage adjustment is difficult, with most clinicians opting for use of the Child-Pugh classification.
6. Genetic polymorphisms affecting the drug metabolizing enzymes represent an additional patient-specific factor to consider in optimization of drug therapy.
7. There are few examples of how metabolic genotypes or phenotypes can determine dosage of individual drugs.
8. There have been increased attempts to incorporate pharmacogenetics in clinical studies during drug development and in regulatory review.

Although there are different patient-related variables that can change the pharmacokinetics of drugs and potentially require dosage regimen modification, the most common dosing changes likely occur with alterations in elimination capacity of the two primary eliminating organs, the liver and the kidneys. This chapter will focus on the changes in drug pharmacokinetics and pharmacodynamics resulting from altered hepatic drug metabolism in patients with hepatic dysfunction, and the implications for dosing. In addition, genetic changes in metabolic capacity of the patient also affect drug elimination from the liver, and examples of how pharmacogenetics have impacted dose modification and labeling is discussed in this chapter.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

DRUG ELIMINATION BY THE LIVER

1 Drugs are primarily eliminated from the body by metabolism and excretion. The liver plays a pivotal role in the metabolism of drugs and formation of metabolites prior to their excretion by the kidneys. The overall capacity of the liver to carry out its metabolic role is primarily dependent on three factors: activity of the metabolizing enzymes within the smooth endoplasmic reticulum and the cytosol of the hepatocyte; the degree of drug protein binding in the blood, which affects the amount of unbound drugs available for uptake into the hepatocyte; and liver blood flow, which delivers drugs to the hepatocyte via the portal vein for orally administered drugs and via the systemic circulation for drugs administered by other routes. Thus, patient-specific factors that affect enzymatic activity, protein binding, or liver blood flow would potentially result in significant alterations in drug disposition and therapeutic response. An understanding of the pharmacokinetic basis of hepatic drug elimination/metabolism is a foundational premise from which one can conceptualize and quantify altered drug disposition in patients with liver dysfunction.

PHARMACOKINETIC BASIS OF HEPATIC DRUG CLEARANCE

Only unbound drugs can be transported from the vasculature to the hepatocyte, where biotransformation, which is dependent on the activity of the relevant metabolic enzymes occurs. Therefore, blood flow to the liver, the degree of plasma protein binding, and the intrinsic metabolic activity, all affect the efficiency of the liver to metabolize a specific drug. The intrinsic metabolic activity, defined as the ability of the hepatocyte to eliminate a given drug in the absence of drug supply limitations such as plasma protein binding and blood flow, reflects the inherent activity of the relevant drug metabolizing enzymes and is quantified as intrinsic clearance (Cl_{int}). The hepatic clearance (Cl_H) is related to the three physiological determinants by the following mathematical relationship:

$$Cl_H = \frac{Q_H \times fu_B \times Cl_{int}}{Q_H + fu_B \times Cl_{int}}$$

where Q_H is hepatic blood flow and fu_B is unbound drug fraction in the blood.

Based on this mathematical relationship, when enzyme activity (Cl_{int}) and fu_B are very low relative to hepatic blood flow, they will become the primary determinants and rate limiting process for hepatic clearance, as $Cl_H \sim fu_B \times Cl_{int}$. On the other hand, when enzyme activity and fu_B are very high in relation to blood flow, Cl_H would approximate hepaic blood flow and be the rate limiting process for hepatic clearance. A more detailed discussion of the complex mathematical relationship between hepatic clearance and the three

TABLE 48-1 Examples of High-Extraction Drugs with Corresponding Reported Percentage Increase in Bioavailability in the Presence of Cirrhosis, and Low-extraction Drugs

High-Extraction Ratio (≥ 0.7) Flow Dependent	Reported increases in bioavailability in presence of cirrhosis	Low-Extraction Ratio (≤0.3) Flow Independent
Labetalol	91%	Diazepam
Midazolam	100%	Erythromycin
Morphine	115%	Phenytoin
Nifedipine	78%	Theophylline
Propranolol	67%	Valproic acid
Verapamil	60%	Warfarin

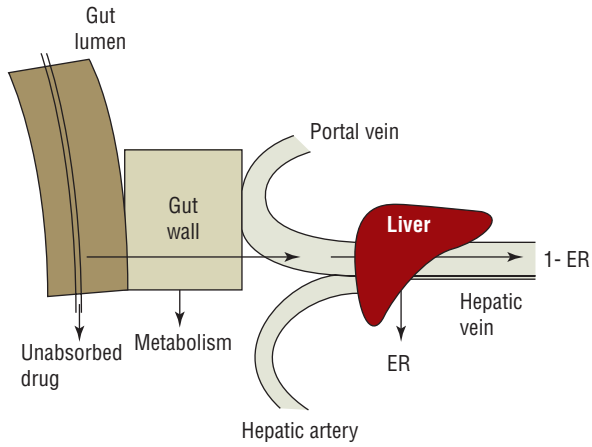

FIGURE 48-1. Schematic representation of the liver integrating the concept of hepatic extraction and first pass effect.

physiological determinants, as well as the different pharmacokinetic models used to explain the physiological approaches to hepatic drug clearance, are provided in the review by Wilkinson.[1]

2 The hepatic clearance for any drug can also be conceptualized as the product of blood flow across the liver and the hepatic extraction ratio (ER_H) for that drug. The ER_H is a semi-quantitative measure of the efficiency of extraction of drug from the blood by the liver that has a numerical value that ranges from zero to 1. High-extraction ratio drugs which have an ER_H ≥0.7 are readily cleared from the blood and more sensitive to changes in, and rate-limited by, hepatic blood flow. Examples of high-extraction ratio drugs with this flow-dependent elimination characteristic are metoprolol, nitroglycerin, and verapamil. Low-extraction ratio drugs—those with an ER_H ≤0.3 are more sensitive to changes in the degree of plasma protein binding and/or intrinsic metabolic activity, and rate-limited by these two factors rather than by hepatic blood flow. They are thus also considered to demonstrate flow-independent elimination. Warfarin, diazepam, and valproic acid are representative examples of low-extraction ratio drugs (Table 48–1).

Although it seems confusing that extensively metabolized drugs such as warfarin, phenytoin, and theophylline are classified as "low-extraction" drugs, it is important to remember that the ER_H does not measure metabolic capacity per se, rather it is a conceptual semi-quantitative measure to help define the ease of extraction of a drug by the liver as the drug is delivered to the hepatocyte. Based on the degree of plasma protein binding, drugs with low-extraction ratio are sometimes further subgrouped as binding sensitive (e.g., phenytoin) and binding insensitive (e.g., theophylline). As such, the mathematical relationship discussed in the preceding paragraph would dictate that hepatic clearance of a highly protein-bound, low-extraction ratio drug would depend on both intrinsic clearance and the degree of plasma protein binding; in contrast, the intrinsic clearance of a drug that is minimally bound to plasma proteins is the primary factor affecting its hepatic clearance.

ALTERED HEPATIC DRUG CLEARANCE IN LIVER DISEASES

Based on the overview of the pharmacokinetic basis of hepatic drug clearance, changes in drug metabolism can result from alterations in hepatic blood flow, plasma protein binding, or intrinsic metabolic activity. While many different pathophysiological liver diseases can result in reduced functional capacity, most acute entities such as hepatitis, liver cancer, and hepatosplenic schistosomiasis are usually not associated with significant or prolonged alterations in drug metabolism. Jorga et al.[2] showed that in patients with moderate chronic hepatitis, there was no difference in the unbound clearance of tolcapone compared with that in healthy volunteers. In contrast, patients with nonalcoholic cirrhosis showed a significant decrease in unbound clearance of tolcapone. In fact, most clinical studies that have investigated the effect of liver diseases on drug disposition have primarily been conducted in patients with cirrhosis.[3]

CHANGES IN HEPATIC BLOOD FLOW

3 The liver is primarily perfused by blood from the hepatic artery, which carries oxygenated blood from the aorta, and the portal vein, which carries nutrient-rich blood from the gastrointestinal tract. The terminal branches of the hepatic artery and the portal vein merge into the hepatic sinusoids and serve as the vascular capillaries of the hepatocyte. The hepatic vein is the conduit by which blood from the liver enters into the inferior vena cava and then the systemic circulation. The portal vein provides about 75% of the liver's total blood supply of about 1.5 L/min in healthy adults. Therefore, the liver is the first site of metabolism for orally administered drugs even before they reach the systemic circulation (Fig. 48–1). This "first pass effect" primarily affects high extraction ratio drugs and the extent of drug elimination can be significant, resulting in low systemic bioavailability (Table 48–1). Simply put, under the assumptions of complete drug dissolution, absence of drug degradation in the gastrointestinal tract, and absence of gut wall metabolism, a drug with ER_H of 70%, will have a bioavailability of 30%. Although the extent of drug metabolism can be circumvented by oral administration of a higher dose compared with that for intravenous administration, the oral bioavailability of some drugs could be very low and variable, necessitating administration by alternative routes such as the sublingual route for nitroglycerin.

In patients with cirrhosis, due to any of the multiplicity of causes (see Chapter 43), blood flow across the liver is usually decreased.[4,5] In addition, cirrhosis also causes alteration of vasculature within the liver, resulting in intra- and extra-hepatic portasystemic shunting. Shunt formation has been shown to allow up to 80% of blood supply to bypass the hepatocytes,[5] and thus does not come in contact with the metabolizing enzymes located therein. Furthermore, the permanent loss of hepatocyte function in patients with cirrhosis also results in reduced metabolic capacity. These two pathological processes together decrease hepatic clearance significantly for orally administered high extraction ratio drugs, and the reduced first pass effect results in a dramatic increase in systemic bioavailability (Table 48–1).[3] Pentikainen et al.[6] reported that in patients without cirrhosis, the oral bioavailability of midazolam is 38%. In patients with cirrhosis, the bioavailability is 76%, representing a two-fold increase. This can have

a significant impact on the likelihood of the patient experiencing an adverse drug reaction and warrant dosage adjustment for patients with liver diseases which will be discussed later in this chapter. In contrast, low-extraction ratio drugs tend to have minimal first pass effects and therefore exhibit high bioavailability after oral administration. As long as additional biological processes, such as gastrointestinal absorption, are not altered then bioavailability will be minimally affected.

CHANGES IN METABOLIC CAPACITY

In addition to altering the liver vasculature, cirrhosis also has been associated with irreversible hepatic damage and cell death. Although extensive hepatic damage is associated with reduced drug metabolism as evidenced by a decrease in Cl_{int} the extent of impairment is variable not only among patients, but also among different metabolic enzymes.

4 In general, phase I oxidative metabolism mediated by the cytochrome P450 (CYP) enzyme system is more sensitive to the effect of cirrhosis than phase II conjugation reactions, especially glucuronidation.[7] For example, among the benzodiazepines, the clearance of diazepam and midazolam, but not of oxazepam and temazepam, are reduced in patients with cirrhosis.[3] This differential effect between phase I oxidation and phase II conjugation reactions may be related to greater sensitivity of the CYP enzyme system to hypoxia as the result of impaired uptake of oxygen caused by sinusoidal capillarization.[8] Indeed hypoxia has been shown to have an important role in suppressing CYP-mediated drug metabolism in both animal[9] and human[10] studies. Frommes et al.[11] have shown that oxygen administration via a face mask in cirrhotic patients resulted in normalization of clearance of the phase I substrate theophylline but not of acetaminophen, a phase II substrate. Other factors that may contribute to the variable sparing effect include activation of latent UDP-glucuronosyltransferase (UGT), increased extrahepatic glucuronidation, differences between specific glucuronidation pathways, and similar to the CYP enzyme system, a differential effect on individual UGT isoforms.[7] Despite the general belief of "sparing" of phase II conjugation reactions in patients with cirrhosis, it is important to note that more recent studies have shown conjugation reactions can be reduced in patients with liver dysfunction, especially those with severe liver cirrhosis (Table 48–2).[2,12–14] The conflicting result between the study of Sonne et al.[13] and Shull et al.[15] could be related to the difference in severity of liver diseases in the two study populations.

Given the presence of multiple isoforms of human cytochrome P450 enzymes, different studies have investigated whether there are selective differences in expression and activity of individual isoenzymes. George et al.[16,17] found that the total CYP amount in the livers obtained from 50 patients with different degrees of end-stage liver disease, Child-Pugh class A to C, was reduced when compared with healthy individuals. Based on the Child-Pugh classification, four of the 50 patients had class A, 17 had class B, and 29 had class C cirrhosis. In addition, 18 patients also had cholestasis.

Selective and variable alterations in amount, catalytic activities, and mRNA level among CYP1A2, CYP2C8/10, CYP2E1, and CYP3A were reported in these 50 patients, and the presence or absence of cholestasis also had an effect on the observed changes. CYP1A2 amount and catalytic activity were significantly reduced with a corresponding decrease in mRNA level in patients with both cholestatic and noncholestatic cirrhosis. CYP3A4 amount, catalytic activity, and mRNA were significantly reduced only in patients without cholestasis. The amount and catalytic activity of CYP2E1 were decreased only in cirrhotic patients with cholestasis, whereas the CYP2E1 mRNA level was lower in both types of cirrhosis. In contrast, CYP2C8/10 amount and catalytic activity were not reduced in either type of cirrhosis. Although the corresponding levels of mRNA were shown to be decreased in both cirrhosis types, the use of a nonspecific polyclonal antibody to identify CYP2C8/10 might have recognized other 2C isoenzymes and produced erroneous results. In summary, while it is clear that based on *in vitro* studies at the protein level,[16,17] the extent of hepatic dysfunction-induced impairment in drug metabolism is dependent on both severity and type of disease, as well as the specific isoenzyme affected, the exact mechanism for this differential effect remains to be elucidated. In addition, the ability to extrapolate these results to the patient care setting and possible dosage recommendation would likely require incorporation of the effect of additional patient-specific variables such as concurrent medications and disease states.

CHANGES IN EXTENT OF PLASMA PROTEIN BINDING

An additional complicating factor occurs for low-extraction, protein-binding sensitive drugs. In patients with cirrhosis, production of drug-binding proteins such as albumin and alpha-1-acid glycoprotein are decreased, resulting in an increase in the unbound concentration of acidic and basic drugs, respectively. The magnitude and duration of the elevated unbound concentration is difficult to predict.

BILIARY EXCRETION AND HEPATIC TRANSPORT OF DRUGS

The biliary tract is important not only for bile secretion, but also for excretion of drugs and metabolites mediated by the APT-binding cassette superfamily of hepatic transporters. Drugs and metabolites that are excreted into the bile reach the small intestine via the biliary tract. Within the small intestine, these metabolites, especially the glucuronides, can be converted back to the parent compound, resulting in reabsorption of both parent and metabolites and thus complete the enterohepatic circulation. Therefore, interruption of this enterohepatic circulation could reduce systemic drug exposure. There is little information on the contribution of biliary excretion to the overall drug elimination and the effect of liver diseases on biliary excretion of drugs is poorly quantitated.

The role of hepatic transport proteins in mediating drug uptake into the hepatocytes and biliary excretion of drugs has been recognized in recent years. Among these hepatic transporters, the organic

TABLE 48-2 Example of Drugs with Documented Changes in Phase 2 Metabolic Capacity in Patients with Liver Diseases

Drug	Types or Severity of Liver Disease	Changes in Pharmacokinetic Parameters	Recommended Dosing Modification	References
Diflunisal	Histologically proven cirrhosis	36% reduction in clearance of unbound diflunisal 38% reduction in formation of phenolic and acyl glucuronides		12
Oxazepam	Biopsy proven cirrhosis	54% reduction in oral clearance		13
Tolcapone	Child-Pugh class B	44% reduction in unbound clearance	50% dose reduction	2
Zidovudine	Child-Pugh class B or C	73% reduction in oral clearance	50% dose reduction	14

anion transporting polypeptide (OATP) and the P-glycoprotein multidrug transporter, or MDR1, have been the most studied. OATP is an uptake transporter which is responsible for the hepatic uptake of organic anions primarily, whereas P-glycoprotein is an efflux transporter that is responsible for the biliary excretion of cationic drugs. Although different human diseases are known to be associated with loss of transporter function,[18] currently there is little specific information regarding how liver disease affects the function of these proteins and therefore hepatic transport in humans. Nevertheless, reduced expression of transporters including OATP2 and MRP2 have been observed in patients with cholestatic liver diseases,[19,20] which could impair excretory liver function. On the other hand, intermittent hypoxia could up-regulate hepatocellular P-glycoprotein expression.[21]

ADDITIONAL EFFECTS OF LIVER DISEASES ON DRUG DISPOSITION AND EFFECTS

EFFECT ON DRUG ABSORPTION

Delayed gastric emptying possibly related to altered action of gastrointestinal hormones, has been shown to occur in patients with cirrhosis.[22] While this will delay the rate of absorption, the extent of drug absorption is generally not reduced. Although the liver has no functional role in affecting the absorption of drug from the gastrointestinal tract per se, its unique anatomical positioning within the circulating system makes it a primary site of loss for orally administered drug prior to its entry into the systemic circulation. As previously discussed, drugs with a high extraction ratio tend to undergo significant "pre-systemic metabolism" or "first pass effect," resulting in low systemic bioavailability. In patients who have cirrhosis with associated portasystemic shunting and/or reduction in metabolic capacity, oral administration of these drugs could result in a significant increase in their systemic bioavailability and hence pharmacodynamic effect. In contrast, drugs with low extraction ratios have been noted to be negligibly affected.

EFFECT ON DRUG EXCRETION

Reduced glomerular filtration rate and renal plasma flow have been observed in patients with liver cirrhosis[23] and patients with liver transplant,[24] potentially accounting for reported decreased renal elimination of commonly used drugs[3] In addition, in individual patients, advanced liver disease can be complicated by the presence of hepatorenal syndrome. In these patients, dosage reduction would need to be considered even for drugs that are primarily excreted unchanged by the kidney. For example, the elimination of the antiepileptic agent levetiracetam is primarily dependent on the kidney, yet a 50% dosage reduction was recommended for patients with severe cirrhosis.[25] It is difficult to assess renal function in patients with liver cirrhosis.[23,24] Most serum creatinine-based equations tend to overestimate the true glomerular filtration rate. This has led some investigators to suggest the use of inulin or iothalamate to measure GFR in patients with advanced liver diseases.[23]

EFFECT ON DRUG PHARMACODYNAMICS

Changes in therapeutic response to a drug can occur in patients with liver disease even in the absence of any changes in pharmacokinetics. Increased drug sensitivity can occur as a result of altered affinity of the drug to its target, altered binding to the target, alteration in the target itself, altered permeability of the blood brain barrier, or increases in GABA-ergic activity or GABA receptors. Altered pharmacodynamic responses have been reported in the literature with analgesics, benzodiazepines, loop diuretics, and beta-blockers.[26]

Bakti et al.[27] reported that with similar unbound triazolam concentration at 2.25 hours after drug administration, cirrhotic patients have an average of 30% greater impairment in psychometric performance tests, including digit symbol substitution test, flicker sensitivity, and pursuit rotor, when compared with healthy control subjects. Test performance was similar in both groups prior to administration of triazolam. The study results suggest that the increased sensitivity is not due to altered pharmacokinetics and might explain why clinically some cirrhotic patients develop encephalopathy and other CNS effects even when administered standard doses of benzodiazepines, cimetidine,[28] and quinolones.[29]

On the other hand, resistance to the pharmacodynamic effects of loop diuretics in patients with cirrhosis has been reported for bumetamide, furosemide, torasemide, and triamterene.[26] For these drugs, the sigmoidal curve that describes the relationship between drug concentration and pharmacological response is shifted to the right, indicating a reduced response compared with healthy individuals. Down-regulation of β_2-adrenoreceptors in patients with cirrhosis[30] has been suggested as a possible mechanism of lower therapeutic response observed with metipranolol[31] in patients with cirrhosis.

LIVER FUNCTION ASSESSMENT

In contrast to renal impairment, accurate quantification of liver function in patients with hepatic impairment is difficult to perform, especially for the purpose of drug dosage adjustment. The severity of liver function impairment is usually assessed clinically with the Pugh modification of the Child-Turcotte classification.[32] Based on the clinical evidence of ascites and encephalopathy and laboratory parameters that measure the liver's synthetic and excretory functions, patients are assigned different scores in accordance to the level of impairment in these parameters (Table 48–3). The classification is easy to use and useful for following the clinical course of an individual patient or comparing groups of patients among studies. It is noteworthy that the Child-Pugh classification does not include assessment of renal function, an important prognostic factor in liver disease. The Model for End-stage Liver Disease (MELD) is a more recently developed, and potentially more objective scoring system for liver disease severity and includes variables such as serum bilirubin, creatinine, and the international normalized ratio (INR) of prothrombin time.[33] However, alterations in the synthesis of albumin

TABLE 48-3 Severity of Liver Disease Based on the Child-Pugh Classification

Clinical or Laboratory Parameters	1 Point	2 Points	3 Points
Ascites	Absent	Mild	Moderate
Encephalopathy (grade)	Absent	Grade 1 or 2	Grade 3 or 4
Serum albumin	>3.5 g/dL (>35 g/L)	2.8–3.5 g/dL (28–35 g/L)	<2.8 g/dL (<28 g/L)
Serum bilirubin	1–2 mg/dL (17.1–34.2 mmol/L)	2–3 mg/dL (34.2–51.3 mmol/L)	>3 mg/dL (>51.3 mmol/L)
Prothrombin time (sec > control)	1–4	4–10	>10

A value of 5 suggests absence of liver impairment, whereas 15 would indicate severe liver failure. Child-Pugh class A = 5 to 6 points, class B = 7 to 9 points, and class C = 10 to 15 points. The original Child-Turcotte classification consisted of grades A, B, and C, with grade C being the most severe liver disease. Similar to the Pugh modification, the Child-Turcotte classification includes albumin, bilirubin, and ascites, plus assessment of nutrition and neurological disorder.

or clotting factors and the corresponding changes in their respective laboratory parameters as well as the presence of patient-specific variables such as nutritional status and vitamin K intake complicate the utility of these parameters in the MELD functional assessment tool. In addition, in contrast to renal impairment, none of the clinically used liver function tests, including those used in the Child-Pugh classification and MELD,[33] correlate well with drug pharmacokinetic parameters. This not only is a result of their inability to quantify the primary physiological determinants of hepatic clearance, including intrinsic clearance and hepatic blood flow, but also a reflection of the complex and multiple physiological processes not being accurately accounted for by any individual laboratory test.

The inability of endogenous markers to provide a quantitative measurement of the liver capacity to metabolize drugs has led to the administration of exogenous model substrates and calculation of their clearances or the extent or rate of formation of their respective metabolite as quantitative liver function measurements.[34] Based on the physiological determinants of hepatic clearance discussed previously, these exogenously administered model substrates can be generally categorized into flow dependent, e.g., indocyanine green, lidocaine, and sorbitol; and flow independent, e.g., aminopyrine, antipyrine, caffeine, and erythromycin.[25] However, none of these markers have been shown to be better than the Child-Pugh classification for assessing liver function in patients. The time required for performing these tests, as well as the invasiveness of some of the procedures associated with specific tests, also limit their clinical utility. Indeed, to date, they have not gained widespread acceptance for predicting drug kinetics and aiding dosage adjustment in patients with liver dysfunction.

Furthermore, studies showed that administration of a flow-dependent and flow-independent model substrate in the same subjects did not result in an independent measure of the physiological determinants of hepatic clearance. Rather, a correlation between the two test measures was unexpectedly obtained.[35,36] Since cirrhosis causes both irreversible hepatic cell damage and altered vasculature via portasystemic shunting, the pharmacokinetic profile of a drug can be affected by changes in hepatic blood flow and drug metabolizing enzyme activity. However, it is not known to what extent reduced hepatocyte function would impact elimination of flow-dependent drugs. Nevertheless, the "intact hepatocyte hypothesis," which suggests the presence of intra-hepatic shunts in chronic liver disease, has been proposed as a possible explanation for the reduced extraction of flow-dependent drugs. This may account for the observed positive correlation between the clearances of both flow-dependent and flow-independent drugs.[35,36] In addition, given the complexity of the CYP enzyme system, simultaneous administration of several model substrates which have specificity for different metabolic enzymes has been advocated and can be accomplished by the administration of various combinations of drugs.[37–39] This so-called "cocktail approach" has been primarily used in the research environment to characterize changes in metabolic capacities in patients with liver dysfunction.

DRUG DOSING IN PATIENTS WITH LIVER IMPAIRMENT

Similar to dosing considerations in patients with kidney dysfunction, drug dosage regimen adjustment in patients with liver diseases can in general be accomplished by either dose reduction, extending the dosing interval, or a combination of both strategies. However, the lack of a clinical laboratory test that correlates well with the metabolic capacity of the liver has hampered the development of dosing guidelines or algorithms. The U.S. Food and Drug Administration (FDA), through official guidance, has suggested the need of dosage adjustment for drugs that exhibit a greater than two-fold increase in AUC in patients with hepatic impairment,[40] although no specific recommendation (e.g., percentage dose reduction or extent of liver impairment) has been provided.

Nevertheless, based on an understanding of the pharmacokinetic basis of hepatic drug metabolism, knowledge of the likely etiology of liver dysfunction (reduced liver blood flow, porta-systemic shunting, or hepatic failure), and characteristics of the drug in question (flow dependent or flow independent, extent of plasma protein binding), a conceptual framework for rational dosing can be made. For orally administered drugs with a high ER_H the initial and maintenance doses in patients with cirrhosis need to be reduced because of the likely significant decrease in first pass effect caused by porta-systemic shunting and decreased hepatic blood flow. The challenge in adopting this conceptual framework to clinical practice is our inability to predict the magnitude of dose reduction needed. Given the data of Pentikainen[6] and the ranges of reported percentage increase in bioavailability for some commonly used drugs (Table 48–1), one prudent approach is to assume 100% bioavailability unless there is specific bioavailability data or dosage adjustment recommendations. If this is the case one can estimate the reduced maintenance dose proportionally by using the following mathematical expression: $D_H/D_N = F/100$, where F is the known bioavailability of the drug in patients without liver disease available from the literature or the manufacturer, and D_H and D_N are the doses used in patients with liver dysfunction and normal liver function, respectively. If drugs with a high ER_H were administered intravenously, then only the maintenance dose would need to be reduced as a result of reduced hepatic blood flow. For drugs with a low ER_H, changes in bioavailability is minimal after oral administration and the initial dose for both oral and intravenous routes could be the same as patients with normal liver function. On the other hand, the maintenance dose for both administration routes would need to be reduced in patients with cirrhosis based on the estimated reduction in metabolic capacity.

For example, the oral dose of theophylline can be reduced by up to 50%, because the clearance is 0.042 L/kg/h in patients with cirrhosis as compared with 0.062 L/kg/h in patients with normal liver function.[41] Similarly, the dosage of tolcapone also is recommended to be reduced by 50% because of the difference in unbound clearance in patients with Child-Pugh class B cirrhosis relative to normal volunteers.[2] Obviously, this dose modification strategy serves only as a starting point. The therapeutic index of the drug in question and good clinical judgment with an awareness of other factors that can further change the metabolic capacity (for example, in the case of theophylline, viral illness, smoking, drug—drug interaction, congestive heart failure) would greatly enhance the ability of a clinician to optimize drug therapy in patients with liver dysfunction.

5 Since there is no equivalent of serum creatinine or creatinine clearance for assisting dosage adjustment in patients with liver dysfunction, the Child-Pugh classification, despite its limitation, is still used primarily by clinicians to assess the extent of liver dysfunction and dose adjustment if needed.[42] Since a total Child-Pugh score of 5 and 15 represent, respectively, normal liver function and severe hepatic impairment, it is reasonable to reduce the maintenance dose by 25% for a drug that is primarily dependent on the liver for elimination (≥65% to 70%) in a patient with a score of 8 to 9. A dose reduction of at least 50% would be prudent for a patient with a score of ≥10. Likewise, Child-Pugh B and C classifications[32,43] could result in similar 50% and 75% reductions, respectively, of the daily maintenance dose. For both classification systems, depending on the severity of the liver dysfunction and clinical judgment, extension of the dosing interval should also be considered. Again, based on the assumption of 100% bioavailability, the extended dosing interval can be estimated proportionally by the following mathematical expression: $T_N/T_H = F/100$, where F is the known bioavailability of the drug in patients without liver disease available from the literature or the manufacturer, and T_H and T_N are the dosing intervals

used in patients with hepatic dysfunction and normal liver function, respectively.

Since the FDA official guidance recommends the use of the Child-Pugh classification to categorize the extent of hepatic impairment in patients,[40] this classification has been employed during drug development as the foundation for the development of dosage recommendations for patients with liver diseases. For example, two- to four-fold increases, respectively, in the AUC of atomoxetine in patients with Child-Pugh B and C classifications, have led to the labeling recommendations of 50% and 75% reduction of the normal dose used in patients with normal liver function.[32,44] A summary of dosage recommendations for 23 recently approved drugs has been published; however, the utility of these data to guide drug therapy decisions in clinical practice is unknown.[45]

PHARMACOGENETIC ALTERATION IN DRUG METABOLIZING ENZYME ACTIVITIES

6 While many factors, including age, gender, smoking, and diet, can influence drug disposition and therapeutic response in individual patients, recent research emphasis has focused on the effect of pharmacogenetics on drug pharmacokinetics and pharmacodynamics. For a more in-depth discussion of the concept of pharmacogenetics and how drug disposition and response are related to specific genotypes and/or phenotypes, please refer to Chapter 9. In that chapter, there is also a tabulation of the most commonly utilized diagnostic substrates for those drug-metabolizing enzymes which exhibit genetic variability. The focus of the subsequent sections of this chapter is to provide information on how pharmacogenetic testing has been reported in the literature and its impact on drug therapy individualization or labeling changes for those drugs that are metabolized by polymorphic enzymes.

Pharmacogenetic testing to identify the presence of altered metabolic activity can be achieved by phenotyping and/or genotyping. In general, a genotype is a trait marker of an individual's metabolic activity for a specific polymorphic enzyme and is independent of time and external factors such as concurrent medications, smoking status, or diet. Phenotyping, on the other hand, represents the metabolic activity at a specific time, which could be susceptible to changes associated with concurrent drug therapy. For most patients receiving concurrent therapy, the phenotype might be the more useful and relevant assessment of metabolic capacity and, hence, the foundational information to guide dosing considerations. For example, in the presence of a potent CYP2D6 inhibitor, the CYP2D6 metabolic capacity of a genotypic extensive metabolizer (EM) could be significantly decreased to a level similar to that of a poor metabolizer (PM).[46] In such a scenario, the metabolic capacity would be more accurately reflected by the phenotype, and the dose of the given CYP2D6 substrate drug in a genotypic EM might need to be reduced.

DOSING IN PATIENTS WITH GENETICALLY ALTERED METABOLIC CAPACITIES

ALTERATION IN PHASE ONE ENZYMES

CYP2C9

Metabolism of the pharmacologically active S-warfarin is almost exclusively mediated by the polymorphic *CYP2C9*, with the **3* allele having a greater influence on its disposition than the **2* allele. A meta-analysis of 39 studies involving 7,907 genotyped patients reported that racemic warfarin doses in patients carrying either of these two allelic variants were 20% to 78% lower compared to those with the wild-type **1* allele.[47] Aithal et al.[48] and Margaglione et al.[49] reported higher incidence of bleeding complications in patients with the **2* or the **3* allele compared with patients with the **1* allele. While these studies[47–50] demonstrate a role for the *CYP2C9* polymorphism in determining warfarin dose requirement and minimizing toxicity, polymorphisms in other target genes could also be relevant. Examples of additional polymorphisms include those affecting the activities of vitamin K 2,3-epoxide reductase complex, subunit 1 (*VKORC1*), γ-glutamyl carboxylase, epoxide hydrolase, calumenin, and protein C, as well as the uptake of vitamin K.[51] Incorporation of the relevant covariates of warfarin dosing in dosing algorithm could further optimize warfarin dosing in clinical practice.[52] Of these, the *VKORC1* polymorphism is mostly defined, with the *G*/*G* genotype as the homozygous wild-type requiring higher warfarin doses than *G*/*A* and *A*/*A* genotypes. Current data suggest that both *VKORC1* and *CYP2C9* are major determinants of warfarin dose, whereas the other genes contribute up to 10% of variation.[51] In August 2007, the FDA revised the warfarin product label to include pharmacogenetic information, and subsequently approved different genetic tests for warfarin dosing.

A recent study using a pharmacogenetic algorithm that incorporated clinical and genetic data to estimate initial dose of warfarin showed better correlation between predicted dose and actual dose requirement, in particular for patients requiring low (≤21 mg/wk) and high (≥49 mg/wk) doses, than a clinical algorithm or a fixed-dose approach.[53] Two recent studies utilized modeling techniques to simulate the potential clinical and economic outcomes of pharmacogenomic-guided dosing in hypothetical patient cohorts treated with warfarin for the first time, and concluded that the relatively high cost ($326 to $570 for *CYP2C9* and *VKORC1* bundled testing) of genotype-guided dosing is associated with modest improvements with respect to quality-adjusted life-years, survival rates, and total adverse event rates. Nevertheless, the investigators also suggested that cost-effectiveness of pharmacogenomic-guided warfarin dosing could be improved in several ways. This includes decreasing genotyping cost by 50%, achieving greater effectiveness in INR-control in clinical outcomes (quality-adjusted life-years, survival rates, and total adverse event rates) with genotype-guided dosing, and applying the genotype-guided dosing algorithm in patients with out-of-range INRs and/or at high risk for hemorrhage.[54,55]

CLINICAL CONTROVERSY

Although scientific evidence suggests the value of clinical testing for *CYP2C9* and *VKORC1* when prescribing warfarin, many clinicians argue against routine use of the genotyping tests until there is evidence of improvement in long-term outcome.[56,57]

CYP2C19

Despite the fact that *CYP2C19* mediates the metabolism of several drugs, including proton pump inhibitors (PPIs), diazepam, and voriconazole, its clinical utility has not been examined as extensively as that of the *CYP2D6* polymorphism. The polymorphic *CYP2C19* is the primary isoenzyme responsible for the metabolism for PPIs. Although there are up to 10-fold differences in systemic exposure between carriers of the *CYP2C19*1* allele versus **2* and **3* alleles, patients possessing one or two of these variant alleles did not experience higher incidence of concentration-related toxicity. This is likely a reflection of the wide margin of safety for these drugs. Rather, the clinical relevance of the *CYP2C19* polymorphism is related to the efficacy of PPIs in erradicating *H pylori*. Compared with *CYP2C19* PMs, higher PPI doses are required in *CYP2C19* EMs to achieve similar drug exposure, intragastric pH, and efficacy.[58] Similar to *CYP2D6*2*, a recently identified *CYP2C19*17* allele is

associated with a very rapid metabolism phenotype and carriers of this allelic variant would likely require higher doses of PPIs for acid suppression.[59,60] Although one study showed no association between *CYP2C19*17* genotype and eradication of *H pylori* for pantoprazole,[61] another study predicted that omeprazole AUC would be lower by about 40% in homozygous carriers of *CYP2C19*17*.[62] Given the higher affinity of omeprazole to CYP2C19 compared with pantoprazole,[63] further studies using omeprazole are required to clarify the clinical relevance of *CYP2C19*17* genotype in determining the success rate of treatment of acid-related disorders.

Furata et al.[64] reported the results of pharmcogenomic-based tailored lansoprazole regimens designed to achieve sufficient acid inhibition for eradication of *H pylori*. Based on 24-hour intragastric pH monitoring in healthy volunteers, lansoprazole dosage regimens that achieved intragastric pH ≥5.0 were documented to be 30 mg 3 times daily for homozygous carriers of the **1* allele, 15 mg 3 times daily for heterozygous carriers of the **1* allele, and 15 mg twice daily for homozygous carriers of the **2* or **3* alleles. For achieving intragastric pH ≥5.8, the corresponding dosage regimens in the three *CYP2C19* genotypes groups were 30 mg 4 times daily, 15 mg 4 times daily, and 15 mg twice daily, respectively. Three hundred *H pylori*-positive patients were then randomly assigned to receive either the standard regimen consisting of lansoprazole 30 mg, clarithromycin 400 mg, and amoxicillin 750 mg, all given twice daily; or the pharmacogenomics-based regimen consisting of lansoprazole dosed according to patient's *CYP2C19* genotype and antibiotic regimen according to genetic testing of bacterial susceptibility to clarithromycin. The eradication rate for the pharmacogenomics-based regimen was 96% (144 of 150 patients), significantly higher than the 70% (105 of 150 patients) achieved with the standard regimen ($P < 0.001$). Including the cost of the genotyping test, the per-patient cost for successful eradication of *H pylori* for the genotype-based regimen ($669) was similar to that of the standard regimen ($657), lending support not only to the clinical usefulness, but also the cost-effectiveness of pharmacogenomic-based therapeutic approach as well.

CYP2C19 polymorphism has also been associated with dosing of the antiplatelet drug clopidogrel, which requires biotransformation to its active metabolite. In 162 healthy subjects, those with at least one reduced-function *CYP2C19* allele had 32.4% lower AUC of the active metabolite, reduced inhibition of platelet aggregation, and decreased pharmacological response ($P < 0.001$). In addition, in 1,477 patients with acute coronary syndromes, higher incidences of cardiovascular events following myocardial infarction were noted in patients with reduced *CYP2C19* function when compared with noncarriers of the reduced-function alleles.[65] This and six other studies were cited in the revised clopidrogel FDA-approved product label (updated May 5, 2009) which noted a 30% to 50% reduction in AUC of the active metabolite in *CYP2C19* intermediate and poor metabolizers after a loading dose of 300 or 600 mg and a maintenance dose of 75 mg daily.[65]

CYP2D6

The report of a female patient found to be resistant to normal doses of nortriptyline[66] represented one of the earliest indications of how altered metabolic capacity can impact drug dosing and response. The clinical observation and subsequent metabolic phenotyping and genotyping identified three extra copies of the *CYP2D6* gene in the patient,[67] thereby accounting for her extremely high dose requirement of 500 mg/day. This patient and others with similar high *CYP2D6* activity were subsequently categorized as ultrarapid metabolizers (UM).

This clinical observation led to a dramatic increase in the identification, cloning, and investigation of the functional significance of numerous additional *CYP2D6* alleles. To date, it is probably safe to label *CYP2D6* as the most studied but yet most variable gene.

TABLE 48-4 Dosage Adjustment (Percentage of Normal Dose) of Selected Antidepressants and Antipsychotics Based on CYP2D6 Genotypes

Drugs	EM	IM	PM	UM
Desipramine	130	80	30	260
Imipramine	130	80	30	
Venlafaxine	130	80	30	
Olanzapine	140	60	40	
Maprotiline	130	80	40	
Trimipramine	130	80	40	
Amitriptyline	120	90	50	
Nortriptyline	120	90	50	230
Risperidone	110	100	50	
Clomipramine	120	90	60	
Fluvoxamine	120	90	60	
S-Flupenthixol	120	90	70	
Fluoxetine	110	90	70	
Mianserine	110	90	70	300
Paroxetine	110	90	70	
Zuclopenthixol	110	90	70	
Haloperidol	110	100	80	

Table adapted from Kirchheiner et al.[70]

The presence of multiple alleles with significant interindividual (20%–96%) and intraindividual (12%–140%) variabilities in enzyme activity[68,69] may be partially responsible for the time gap between the nortriptyline case report and subsequent attempts to utilize metabolic genotype or phenotype to generate antidepressant dose recommendations.[70] The investigators compared the pharmacokinetic profiles of 32 CYP2D6- and CYP2C19-dependent antidepressants in subjects with an array of *CYP2D6* and *CYP2C19* genotypes. The analysis took into consideration the contribution of the polymorphic isoenzymes to the overall elimination of each antidepressant, and provided dose recommendation for 14 of the 32 antidepressants in EMs, intermediate metabolizers (IMs), and PMs of *CYP2D6* (Table 48–4) or *CYP2C19*. In general, PMs need about 50% of normal dose of tricyclic antidepressants, whereas the dose reduction was smaller for the selective serotonin reuptake inhibitors (SSRIs).

Using the approach proposed by Kirchheiner et al.,[70] nortriptyline maintenance dose requirements for attainment of comparable systemic exposure were estimated to be 50% in PMs and up to 230% of the average dose in UMs. Though there are multiple literature reports of increased incidence of antidepressant adverse effects in PMs of *CYP2D6*, there were no other documented reports of therapeutic failure for CYP-dependent antidepressants in UMs. Kirchheiner et al.[70] acknowledged the lack of data preclude any dose recommendation in UMs for most antidepressants, with the exception of nortriptyline, desipramine, and mianserin. They further noted that only five of 54 reviewed studies included evaluation of efficacy in relation to genotypes, and only the study of Mihara et al.[71] showed a significant relationship ($P = 0.023$). More recently, Brockmoller et al.[72] reported that the clearance of S-mirtazapine in UMs was 12.6-fold higher than in PMs, and suggested that poor response might occur in UMs as a result. Although this data suggests the need for a higher dosage for UMs, no specific recommendations were made.

The formation of the active metabolite *O*-desmethyltramadol from tramadol is dependent on CYP2D6, and similar to codeine, analgesic relief from tramadol has been reported to be lower in PMs.[73] Although tramadol also possess other opioid and non-opioid-dependent mechanisms for its analgesic effect, Stamer et al.[74] have shown in a prospective study of 300 patients recovering from abdominal surgery, a significant difference in the percentage of nonresponders (based on need for rescue pain medication and patient's satisfaction upon interview) between *CYP2D6* PMs (46.7%) and EMs (21.6%)

($P = 0.005$). They also reported a difference in the postoperative analgesic dose requirement of tramadol between the two groups: 144.7 ± 22.6 mg in PMs and 108.2 ± 56.9 mg in EMs ($P < 0.001$). In the recovery room 43.3% of genotypic PMs compared with 21.6% of genotypic EMs required rescue medication. The authors concluded that PMs required higher analgesic consumption to achieve pain relief. Even though there are likely other significant pharmacogenetic variables affecting opioid analgesic response, the difference in dosing requirement shown in this study suggests that 30% dose increases might be necessary in patients who are *CYP2D6*-poor metabolizers. Similar to the PMs, the presence of *CYP2D6*10* allele in intermediate metabolizers has also been associated with reduced tramadol efficacy.[75]

The anticancer drug tamoxifen is metabolized by *CYP2D6* to its active metabolite endoxifen. Recently, a robust correlation between the *CYP2D6* genotype and endoxifen concentration was noted; PMs had a reduced relapse-free time and disease-free survival rate.[76,77] Although many studies had tested for an association between the *CYP2D6* genotype and clinical response to tamoxifen, most of the trials involved a relatively small number of patients. Currently, the FDA has not revised the product label of tamoxifen.

CLINICAL CONTROVERSY

Currently there is no consensus about the use of *CYP2D6* genotyping testing in patients prescribed tamoxifen. Some clinicians advocated its use, especially in postmenopausal women who are *CYP2D6* PM, where aromatase inhibitors would be a valid alternative therapeutic choice. Opponents of the practice argue that routine use of the genotype test should await more reliable evidence from well-designed studies. On the other hand, the clinical implication of *CYP2D6* metabolic status is more relevant for prescribing concurrent therapy that might interact with tamoxifen via *CYP2D6* inhibition. When prescribing antidepressants in breast cancer patients for management of depression and/or vasomotor symptoms, choice of antidepressants should take into consideration their inhibitory effect on CYP2D6.[46,78]

CYP3A

Despite the existence of significant interindividual variability in activity, evaluations of the role of *CYP3A* genes (*CYP3A4*, *CYP3A5*, and *CYP3A7*) in mediating disposition and response have not been conclusive. The most convincing evidence showing a genetic influence on tacrolimus pharmacokinetics has been demonstrated in patients with the **3* allele of *CYP3A5*3*. Homozygous carriers of the **3* allele had a higher plasma tacrolimus concentration compared to patients with the *CYP3A5*1* allele, although considerable overlap was noted.[79,80] MacPhee et al.[81] showed that homozygous and heterozygous carriers of the *CYP3A5*1* allele required a longer time to achieve therapeutic concentrations and suggested these individuals be prescribed an initial tacrolimus dose that is twice normal. Given that it is common clinical practice to measure tacrolimus concentrations, this genotype-based dose modification recommendation could be readily tested. Based on current pharmacogenetic information, dosing information cannot be predicted nor are dosage modifications recommended for cyclosporine or sirolimus.[82]

ALTERATION IN PHASE 2 ENZYMES

Thiopurine Methyltransferase

6-Mercaptopurine and azathioprine are used in the management of childhood acute lymphoblastic leukemia and autoimmune and inflammatory diseases such as rheumatoid arthritis. S-methylation of these drugs is mediated by the polymorphic thiopurine S-methyltransferase (TPMT). PMs and IMs with two and one deficient *TPMT* allele, respectively, are prone to significant hematopoietic adverse effects when given standard doses. Currently, it is well established that PMs and IMs would need a maximum of 10% to 15% and 50%, respectively, of the normal dose of thiopurines.[83] The identification of a patient's *TPMT* genotype prior to therapy initiation has been adopted as a standard procedure in some hospitals in the United States.[84] In a recent study, Fargher et al.[85] reported that 67% of National Health Service clinicians in England routinely utilize *TPMT* phenotyping compared with approximately 5% who use genotyping to guide prescribing and monitoring of azathioprine. Investigators reported that screening for *TPMT* gene mutations for all patients prior to starting azathioprine is cost-neutral if only homozygous carriers of the mutation suffer from myelosuppression. Screening would become cost beneficial if heterozygous carriers of the mutations also experienced myelosuppression.[86] Additional documentation of cost-effectiveness of the strategy,[86,87] expanded education of clinicians, and further availability of commercial tests for determination of *TPMT* genotype and phenotype may make it easier to justify and implement genotype-based thiopurine dosing into clinical practice.

Uridine Diphosphate Glucuronosyltransferase

The uridine diphosphate glucuronosyltransferase 1A1 (UGT1A1) is involved in the glucuronidation of several anticancer drugs including irinotecan. Irinotecan is a prodrug and the pharmacologically active moiety, SN-38, is inactivated by UGT1A1. Thus, PMs of UGT1A1 have a higher incidence of dose-limiting toxicities.[88] A prospective clinical pharmacogenetic study has shown a correlation between the development of grade 4 neutropenia and patients who are homozygous carriers of the *UGT1A1*28* allele.[89] In fact, the product label for irinotecan has been updated to reflect the need of reducing initial dose by at least one level (e.g., from 250 mg/m^2 to 125 mg/m^2) in homozygous carriers of the *UGT1A1*28* allele (Table 48–4).

N-Acetyltransferase

The bimodal distribution of isoniazid's acetylation capacity, which was demonstrated several decades ago, explained the higher incidence of peripheral neuropathy and hepatotoxicity seen in slow acetylators (SAs) compared with rapid acetylators (RAs).[90] Years later, genotyping studies confirmed an inverse relationship between the numbers of active *NAT2* allele and the risk of hepatotoxicity: 28-fold and 4-fold increases in relative risk were noted for patients with no active and one active *NAT2* allele, respectively, when compared to patients with two active *NAT2* alleles.[91,92] Currently two large phase III studies of isoniazid in European and Asian countries are enrolling patients to determine the utility of *NAT* genotype-based dosing (2.5 mg/kg twice weekly for SAs and 7.5 mg/kg twice weekly for RAs) in reducing toxicity in SAs and early treatment failure in RAs. The trials are expected to be completed in late 2011 to early 2012. (See Isoniazid Dose Adjustment According to NAT2 Genotype, *http://www.clinicaltrials.gov*.)

POTENTIALS, CHALLENGES, AND LIMITATIONS OF PHARMACOGENETIC SCREENING AS A PHARMACOTHERAPY DOSING TOOL

8 The above cited examples suggest that there is great potential value associated with the use of pharmacogenetic screening of patients to optimize therapy. The value of early detection of patients with deficient metabolic genotype and/or phenotype is clearly demonstrated with the thiopurines and irinotecan, whereas clinical experience with nortriptyline[66,67] and ondansetron[93] showed that optimal therapeutic response can be achieved earlier in UMs. Given the data on poorer

clinical outcome in *CYP2D6* PMs receiving tamoxifen,[76,77] it will likely be of significant value to implement this pharmacogenetic knowledge into clinical practice. Although there is no documented report of an association between metabolic polymorphisms and SSRI efficacy, PMs were shown to have significant side effects with venlafaxine[94] and paroxetine.[95] Given the high incidence of nonadherence to antidepressants,[96,97] one can also make a case that genotype-based dose reduction in PMs might improve therapeutic outcome, lower the incidence of side effects, and improve adherence to the medication regimen.

7 Despite the expanding body of beneficial evidence, the pace of incorporation of pharmacogenetic-guided individualized therapy into clinical practice has been slow.[98] Currently, pharmacogenetic screening for deficiency in TPMT is one of the few examples of how pharmacogenetics can enhance the individualization of thiopurine drug therapy.[85] The updated product labels of irinotecan and clopidogrel lack specific and quantitative information regarding dose reduction for homozygous or heterozygous carriers of the respective reduced-function alleles and to date genotype-based dosing information is not available for most other drugs. Given the extensive literature on genotype-related differences in drug pharmacokinetics, the incorporation of dosing information into clinical practice has been slow. For example, clearance of tolbutamide in homozygous carriers of *CYP2C9*3* was 84% lower than that in subjects with the *CYP2C9*1/*1* genotype, whereas heterozygous carriers of the **2* allele have about 50% lower clearance.[99] Based on these results, dose reductions of about 90% and 50% would seem to be an appropriate recommendation in these patients for controlled clinical trials to evaluate whether the goal of genotype-based therapy could be achieved in clinical practice. However, to date, such a prospective trial has not been carried out. Since efficacy of the oral sulphonylureas can be evaluated easily in clinical practice, implementation of these dose recommendations in clinics or physician's office in lieu of expensive and time consuming clinical trials might be the first step to take in achieving pharmacogenetic-based dosing and therapy individualization.

Yet it is clear that not all drugs are candidates for genotype-guided dose recommendation. The drug in question not only has to be primarily metabolized by a polymorphic enzyme, it also needs to have a narrow therapeutic index. Based on the knowledge of their pharmacology, the SSRIs would not be good candidates, and it is not surprising that the Evaluation of Genomic Applications in Practice and Prevention Working Group does not recommend the application of pharmacogenomics for these agents.[100] In the study of Brockmoller et al.,[101] although there was a trend towards lower haloperidol efficacy in UMs and higher efficacy in the PMs, there was significant overlap in the haloperidol daily doses among the four metabolic groups, with 14 ± 10 mg in UMs versus 13 ± 9 mg in the PMs. This could be due to the complex metabolic disposition of haloperidol that includes CYP2D6- and CYP3A4-mediated oxidation, glucuronidation, and interconversion with reduced haloperidol. The clinical utility of *CYP2D6* genotyping is further minimized by significant interethnic variabilities in metabolic disposition,[102] and possibly the difficulty of relating rating scale-based changes in psychotic symptoms to specific metabolic genotypes. In addition, as demonstrated with risperidone, the presence of an active metabolite would also make it difficult to demonstrate the clinical relevance of genotype-based dose recommendation for the parent compound.

8 Nevertheless, it is encouraging to find that pharmaceutical companies have chosen to include pharmacogenetic screening to identify special populations for evaluation of pharmacokinetics, pharmacodynamics, and clinical outcomes during the drug development process.[103] As an example, *CYP2D6* genotype was one of the patient-related variables included in the evaluation of differences in systemic exposure of atomoxetine and an 8- to 10-fold increase in AUC and higher incidence of adverse effects was noted in the PM population.[104] Although no specific dose recommendation arose from the results, the information was incorporated into the drug labeling.[44]

As additional data regarding the clinical relevance of pharmacogenetic screening for dosing and therapy individualization become available, the information can be incorporated not only for drugs in development but also for drugs that have been approved. It is noteworthy that over the years, the FDA has updated the product labels of more than 200 drugs to include pharmacogenetic information. This information is in general divided into three categories: pharmacogenetic test either (1) required or (2) recommended for therapeutic decision making, and (3) the availability of pharmacogenetic test is for information purposes only. Specifically, the labeling of 5-mercaptopurine, azathioprine, irinotecan, and clopidogrel were revised to reflect the risk of toxicity and/or the lack of efficacy, as well as the need of dosage adjustment in PMs and IMs. The FDA has also approved the AmpliChip CYP genotyping test (Roche Diagnostics) for screening of common *CYP2C19* and *CYP2D6* alleles, and the UGT1A1 Molecular Assay (Third Wave Technologies) for genotyping *UGT1A1* alleles.[105,106] However, due to lack of study data using patients' individualized genotypes, the revised label information does not specifically address the precise dose reduction for patients receiving any of these drugs (Table 48–5).

TABLE 48-5 Examples of Label Changes Incorporating Pharmacokinetic Data or Therapeutic Response in Patients with Liver Diseases or Genetic Alteration in Metabolic Capacity

Drug	Relevant Pharmacokinetic Data or Therapeutic Response as a Result of Patient-Specific Alteration in Disposition	Label Information Incorporating Study Data
Atomoxetine[104]	4-fold and 2-fold increases in AUC in patients with Child-Pugh C and B classification, respectively	Reduce normal dose by 75% and 50%, respectively, in the two groups of patients.
	5 to 10-fold increases in C_{max} and AUC in CYP2D6 PMs	Blood levels in PMs are similar to those attained by taking strong inhibitors of CYP2D6. The higher blood levels in PMs lead to a higher rate of some adverse effects.
6-Mercaptopurine[83]	6-MP is inactivated via TPMT to the inactive metabolite methyl-6-MP. TPMT activity is controlled by a genetic polymorphism, with a defined correlation between deficiency in TPMT activity and myelotoxicity	Patients with intermediate TPMT activity may be at increased risk of myelotoxicity if receiving conventional doses of 6-MP. Patients with low or absent TPMT activity are at an increased risk of developing severe, life-threatening myelotoxicity if receiving conventional doses of 6-MP. TPMT genotyping or phenotyping (red blood cell TPMT activity) can help identify patients who are at an increased risk for developing 6-MP toxicity. The optimal starting dose for homozygous deficient patients has not been established.
Irinotecan[89]	Irinotecan is converted to the active metabolite SN-38, which is subsequently inactivated by UGT1A1. Irinotecan toxicity is related to SN-38 exposure	Individuals homozygous for the *UGT1A1*28* allele are at increased risk for Neutropenia after irinotecan administration. A reduction in the starting dose by at least 1 level of irinotecan should be considered for patients known to be homozygous for the *UGT1A1*28* allele. The appropriate dose reduction in this patient population is not known.

CONCLUSION

Pharmacogenetics has the potential to improve drug therapy in patients. However, variations in multiple genes that affect both the pharmacokinetics and pharmacodynamics of the candidate drugs present significant challenges in identifying specific gene-variant combinations that can help clinicians achieve optimal therapeutic outcomes for their patients. In addition, few studies address the cost-effectiveness of genomic-guided dosing. Additional clinical trials, similar to the study of Furuta et al.[64] and the ongoing *NAT2* genotype-guided treatment evaluation need to be done before pharmacogenetics-guided dosing can be routinely recommended in clinical practice.

ABBREVIATIONS

AUC: area under the curve

Cl_H: hepatic clearance

Cl_{int}: intrinsic clearance

CYP: cytochrome P450

EM: extensive metabolizer

ER_H: hepatic extraction ratio

fu_B: unbound drug fraction in the blood

CHAPTER 49

Celiac Disease

ROBERT A. MANGIONE AND PRITI N. PATEL

KEY CONCEPTS

1. Celiac disease is a chronic, inflammatory autoimmune disorder caused by intolerance to gluten found in wheat, barley, rye, and other foods when a genetically predisposed person is exposed to the environmental trigger, gluten.
2. Celiac disease is common in Europe and North America, affecting between 1 in 100 to 1 in 120 adults, and 1 in 80 to 1 in 300 children.
3. The integrity of the tissue junctions of the intestinal epithelium is compromised in patients with celiac disease; this enables gluten to reach the lamina propria. The presence of gluten in the lamina propria and an inherited combination of genes contribute to the heightened immune sensitivity to gluten that is found in patients with celiac disease.
4. The classic presenting symptom in adults is diarrhea, which may be accompanied by abdominal pain or discomfort; however, it is noteworthy that during the last decade it has been reported that diarrhea has been the main presenting symptom of celiac disease in less than 50% of cases.
5. Dermatitis herpetiformis is a skin manifestation of celiac disease. All patients with celiac disease will not develop dermatitis herpetiformis; however, all patients with dermatitis herpetiformis are considered to have celiac disease.
6. The frequency of diagnosis of patients with celiac disease has increased; however, the majority of patients with this condition remain undiagnosed.
7. A confirmed diagnosis of celiac disease requires both positive findings on duodenal biopsy and a positive response to a gluten-free diet. The most common serologic markers that are used for screening patients are serum immunoglobulin (IgA) endomysial antibodies and IgA serum anti-tissue transglutaminase antibodies.
8. Strict, lifelong adherence to a gluten-free diet is the only treatment for celiac disease.
9. Clinicians must evaluate the patient with celiac disease for nutritional deficiencies (including folic acid, vitamin B12, fat-soluble vitamins, iron, and calcium) due to malabsorption. Iron-deficiency anemia may be the only presenting sign of disease in patients without diarrhea.

The complete chapter, learning objectives, and other resources can be found at **www.pharmacotherapyonline.com**.

1 Celiac disease is a chronic, inflammatory autoimmune disorder caused by an intolerance to ingested gluten, a storage protein found in wheat, barley, and rye. Genetic, environmental, and immune factors all play a role in the development of celiac disease. The mainstay of treatment of the disease is strict adherence to a gluten-free diet.

A disease resembling celiac disease was first described by a Greek physician in the second century AD.[1] In the mid-1900s, the connection between the ingestion of cereals and celiac disease was made. For many years, celiac disease was considered a disease of childhood with primarily gastrointestinal symptoms. It is now recognized as a disease of all ages with varied presentation.

Also known as celiac sprue, nontropical sprue, and gluten-sensitive enteropathy, the disease is characterized by both gastrointestinal and extraintestinal symptoms. Chronic inflammation caused by exposure to gluten leads to gastrointestinal discomfort, nutrient malabsorption, and systemic complications. Gastrointestinal symptoms, including diarrhea, cramping, bloating, and flatulence, are the "classic" symptoms; however, a patient with celiac disease may initially present with a variety of extraintestinal symptoms. Patients with silent celiac disease have no or minimal symptoms but manifest mucosal damage on biopsy and have positive serologic testing. Patients with celiac disease classified as latent are asymptomatic patients who may show positive serology, have the human leukocyte antigen (HLA)-DQ2 and/or DQ8 haplotype, but have normal mucosa on biopsy.[2]

Adherence to a gluten-free diet is essential because it improves symptoms and prevents long-term complications of celiac disease, which include T-cell lymphomas, small bowel adenocarcinoma, and esophageal and oropharyngeal carcinomas.[3]

RENAL DISORDERS

CHAPTER 50

Clinical Assessment of Kidney Function

THOMAS C. DOWLING

KEY CONCEPTS

1. The stage of chronic kidney disease (CKD) should be determined for all individuals based on the level of kidney function, independent of etiology, according to the National Kidney Foundation (NKF) Kidney Disease/Dialysis Outcome Quality Initiative CKD classification system.
2. Persistent proteinuria indicates the presence of CKD.
3. Quantitation of urine protein excretion, such as the measurement of a spot urine albumin-to-creatinine ratio, is recommended for determining the severity of CKD and monitoring the rate of disease progression.
4. The glomerular filtration rate (GFR) is the single best indicator of kidney function.
5. Measurement of the GFR is most accurate when performed following the exogenous administration of inulin, iothalamate, or radioisotopes such as technetium 99m diethylenetriamine pentaacetic acid (^{99m}Tc-DTPA).
6. Equations to estimate creatinine clearance or GFR are commonly used in ambulatory and inpatient settings and incorporate patient laboratory and demographic variables, such as serum creatinine, cystatin C, age, gender, weight, and ethnicity.
7. Longitudinal assessment of GFR and proteinuria is important for monitoring the efficacy of therapeutic interventions, such as angiotensin-converting enzyme inhibitors and angiotensin receptor blockers, which are used to slow or halt the progression of kidney disease.
8. The measurement of S_{cr} alone, evaluation of a plot of the reciprocal of S_{cr} versus time, and serum cystatin C concentration should be used with caution to estimate the rate of decline in renal function in patients with CKD, as these indices do not consider patient age, lean body mass, gender, diet, concomitant diseases and drug therapy, circadian rhythm, stability of kidney function, or tubular secretion of creatinine.
9. Other assessments of the kidney, such as radiography, computed tomography, magnetic resonance imaging, sonography, and biopsy, are mainly used for determining the diagnosis of a given condition, as they provide evidence of the functional and structural changes associated with kidney disease.

Chronic kidney disease (CKD) is an increasingly alarming worldwide health concern, with nearly 2 million people in the United States alone estimated to require hemodialysis or kidney transplantation by 2030. In response to this widespread problem, the National Kidney Foundation (NKF) has developed a standardized approach for the identification and classification of individuals with CKD and their subsequent stratification into risk categories for end-stage renal disease (ESRD) (see Chapter 52).[1,2] These efforts have heightened the awareness of the need for early identification of patients with CKD and the importance of monitoring kidney function in the clinical setting.

Assessment of renal function using both qualitative and quantitative methods is an important part of the evaluation of patients and an essential characterization of individuals who participate in clinical research investigations. Estimation of creatinine clearance (CL_{cr}) has been considered the clinical standard for assessment of renal function for more than 40 years; however, new methods to estimate the glomerular filtration rate (GFR) are now used in many clinical settings to identify patients with CKD. Other tests, such as urinalysis, radiographic procedures, and biopsy, are also useful for determining the pathology and etiology of kidney disease. Urinalysis, for example, may give clues to the primary location (e.g., glomerular or tubular) of the renal disease. Follow-up studies, such as imaging procedures and kidney biopsy, may then further differentiate the specific cause, thereby guiding the selection of the optimal therapeutic intervention.

1 Quantitative indices of GFR or CL_{cr} are considered the most useful diagnostic tools for the identification of the presence of CKD. These measures can also be used to quantify changes in function that may occur as a result of disease progression, therapeutic

intervention, or a toxic insult.[3] The measurement or estimation of creatinine clearance, however, remains the most commonly used index for individualizing medication dosage regimens in patients with acute and chronic kidney disease. Furthermore, CL_{cr} has been the chief index used to stratify patients in pharmacokinetic studies that serve as the basis for the design of renal dosing algorithms in Food and Drug Administration (FDA) approved package inserts and tertiary drug information sources.[4] The composite term *renal function* includes the processes of filtration, secretion, and reabsorption, as well as endocrine and metabolic functions. Alterations of all five renal functions, whether declining or improving, are associated primarily with GFR. This chapter critically evaluates the various methods that can be used for the quantitative assessment of kidney function in individuals with normal renal function, as well as in those with CKD and acute renal failure (Table 50–1). Where appropriate, discussion regarding the qualitative assessment of renal function is also presented, including specialized tests such as kidney biopsy.

EXCRETORY FUNCTION

The most important contribution of the kidney to overall maintenance of body homeostasis is the urinary excretion of water, electrolytes, endogenous substances such as urea, and environmental toxins. Through the combined processes of glomerular filtration, tubular secretion, and reabsorption, the nephron, as the functional unit of the kidney, regulates the output of water, electrolytes, and solutes from the body and is the key organ responsible for maintenance of homeostasis despite fluctuations in dietary ingestion.

TABLE 50-1 Markers of Renal Function

Renal plasma/blood flow	*p*-aminohippurate (PAH) ^{131}I-orthoiodohippurate (^{131}I-OIH) ^{99m}Tc-mercaptoacetyltriglycine (^{99m}Tc-MAG3)
Glomerular filtration rate	Inulin, sinistrin Iothalamate Iohexol ^{99m}Tc-diethylenetriaminepentaacetic acid (^{99m}Tc-DTPA) ^{125}I-iothalamate Creatinine Cystatin C
Tubular function	*p*-aminohippurate (PAH) *N*^{1}-methylnicotinamide (NMN) Tetraethylammonium (TEA) β_2-microglobulin Retinol-binding protein (RBP) Protein HC (α_1-microglobulin) *N*-acetylglucosaminidase (NAG) Alanine aminopeptidase (AAP) Adenosine-binding protein (ABP)

FILTRATION

Glomerular filtration is a passive process by which water and small molecular weight ions (<5–10 kDa) and molecules diffuse across the glomerular capillary membrane into the Bowman capsule and then enter the proximal tubule (Fig. 50–1). Because most proteins are too large (>60 kDa) to be substantially filtered, or their filtration is impeded by the electronegative charge on the epithelial surface of the glomerulus, compounds presented to the glomerulus in the protein-bound state are not filtered and thus remain in the peritubular circulation.

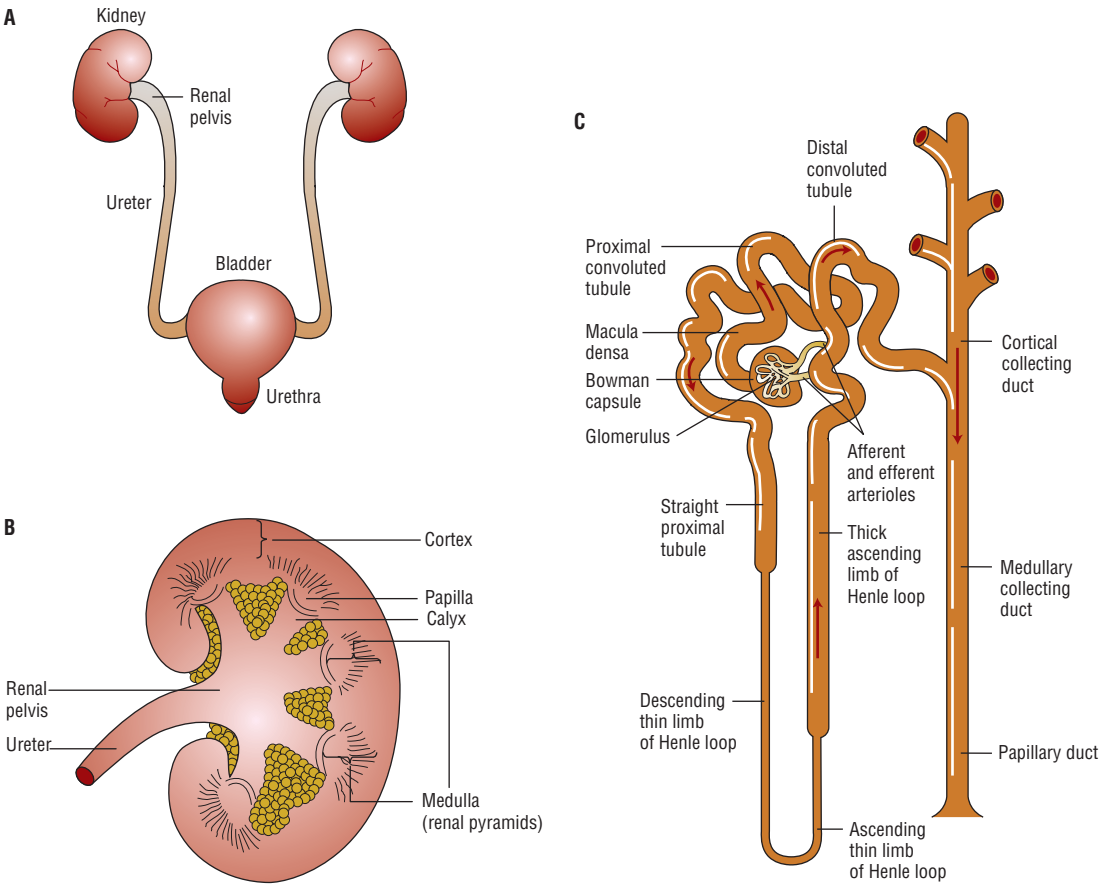

FIGURE 50-1. Structures of the *(A)* urinary system, *(B)* kidney, and *(C)* nephron, the functional unit of the kidney.

SECRETION

Secretion is an active process that mainly takes place in the proximal tubule and facilitates the elimination of compounds from the renal circulation into the tubular lumen. Several highly efficient anionic and cationic transport systems for a wide range of endogenous and exogenous substances have been identified, and the renal clearance of these actively secreted entities can greatly exceed GFR; for example, their clearance may be in the range of 600 to 1,000 mL/min (10–16.7 mL/s). Probenecid, *p*-aminohippurate (PAH), and penicillin are examples of anionic substances; creatinine, cimetidine, and procainamide are well-characterized cations.[5] These transport systems are not mutually exclusive, as probenecid has been observed to compete with the tubular secretion of cimetidine.[6] Other transport pathways, such as P-glycoprotein and multidrug resistance protein, are also present in several tissues, including the kidney, liver, jejunum, colon, and brain. These efflux proteins are now recognized as important contributors to the renal elimination of many drugs.[7] For example, P-glycoprotein, which is located on the apical membrane of the proximal tubule, plays an important role in the renal elimination of a wide range of drugs, such as cimetidine, digoxin, and procainamide. Blockade of P-glycoprotein could result in decreased renal elimination of such compounds, leading to an increased drug exposure. Verapamil and cyclosporine are the two most widely studied agents that reduce the activity of this tubular transport mechanism.[8] The net process of tubular secretion for drugs is therefore likely a result of multiple secretory pathways acting simultaneously.

REABSORPTION

Reabsorption of water and solutes occurs throughout the nephron, whereas the reabsorption of most medications occurs predominantly along the distal tubule and collecting duct. Urine flow rate and physiochemical characteristics of the molecule influence these processes: highly ionized compounds are not reabsorbed unless pH changes within the urine increase the fraction unionized, so that reabsorption may be facilitated.

INTACT NEPHRON HYPOTHESIS

The intact nephron hypothesis described by Bricker,[9] which was published more than 40 years ago, proposes that kidney function of patients with renal disease is the net result of a reduced number of appropriately functioning nephrons. As the number of nephrons is reduced from the initial complement of 2 million, those that are unaffected compensate; that is, they hyperfunction. The cornerstone of this hypothesis is that glomerulotubular balance is maintained, such that those nephrons capable of functioning will continue to perform in an appropriate fashion. Extensive studies have shown that single-nephron GFR increases in the unaffected nephrons; thus, the whole-kidney GFR, which represents the sum of the single-nephron GFRs of the remaining functional nephrons, may remain close to normal until there is extensive injury. Based on this, we would presume that a measure of one component of nephron function could be used as an estimate of all renal functions. This, indeed, has been and remains our clinical approach.

FILTRATION CAPACITY

GFR is dependent on numerous factors, one of which is protein load. Bosch[10] suggested that an appropriate comprehensive evaluation of renal function should include the measurement of "filtration capacity" of the kidney. This is similar in context to a cardiac stress test. The patient may have no hypoxic symptoms, for example, angina while resting, but it may become quite evident when the patient begins to exercise. Subjects with normal renal function administered an oral or IV protein load prior to measurement of GFR have been noted to increase their GFR by as much as 50%. As renal function declines, the kidneys usually compensate by increasing the single-nephron GFR. The renal reserve, the maximal degree by which GFR can be increased, will be reduced in those individuals whose kidneys are already functioning at higher than normal levels because of preexisting renal injury. Thus, this may be a complementary, insightful index of renal function reserve for many individuals with as yet unidentified CKD.

Not only is quantification of renal function an important component of a diagnostic evaluation, but it also serves as an important parameter for monitoring therapy directed at the etiology of the diminished function itself, thereby allowing for objective measurement of the success or failure of treatment. Measurement of renal function also serves as a useful indicator of the ability of the kidneys to eliminate drugs from the body. Furthermore, alterations of drug distribution and metabolism have been associated with the degree of renal function. A discussion of pharmacokinetic changes in renal disease is extensively reviewed in Chapter 57. Although several indices have been used for the quantification of filtration capacity or GFR in the research setting, estimations of creatinine clearance and GFR are the primary approaches used in the clinical arena.

ENDOCRINE FUNCTION

The kidney synthesizes and secretes many hormones involved in maintaining fluid and electrolyte homeostasis. Secretion of renin by the cells of the juxtaglomerular apparatus and production and metabolism of prostaglandins and kinins are among the kidney's endocrine functions. In addition, in response to decreased oxygen tension in the blood, which is sensed by the kidney, erythropoietin is produced and secreted by peritubular fibroblasts. Because these functions are related to renal mass, decreased endocrine activity is associated with the loss of viable kidney cells. In the presence of stages 3 to 5 CKD and moderate to severe acute renal injuries, secretion of erythropoietin is impaired, leading to reduced red blood cell formation; normocytic anemia, and symptoms of reduced oxygen delivery to tissues, such as fatigue, dyspnea, and angina (see Chapters 52 and 53). Renal anemia is clearly associated with many comorbidities, such as left ventricular hypertrophy, which is present in over 40% of patients with CKD.[11] Indeed, anemia-induced renal hypoxia results indirectly in erythropoietin gene activation, tubular necrosis, and apoptosis, thereby contributing to further renal cell injury.[12] This cyclic relationship between kidney disease, suppression of erythropoietin secretion, and cardiovascular disease is also referred to as the cardiorenal anemia syndrome.

METABOLIC FUNCTION

The kidneys perform a variety of metabolic functions, including the activation of vitamin D_3, gluconeogenesis, and metabolism of endogenous compounds such as insulin, steroids, and xenobiotics. Impaired renal function results in decreased formation of activated vitamin D_3 and decreased insulin metabolism. It is common for patients with diabetes and chronic renal failure to have reduced requirements for exogenous insulin,[13] and supplemental therapy with activated vitamin D_3 (calcitriol) or other vitamin D analogues (paricalcitol and doxercalciferol) is often necessary to avert the bone loss and pain associated with renal osteodystrophy.[14] Cytochrome

TABLE 50-2 Presentation of Chronic Kidney Disease (CKD)

	Early CKD (Stages 1–2)	Late CKD (Stages 3–4)
General	Patient may not appear in distress	Patient may have edema
Symptoms	Not likely present	Patient may have fatigue, malaise, pruritus, and/or nausea
Signs	Not likely present	May present with fluid retention, anemia, dyspnea, or reduced urine output
Laboratory tests	Microalbuminuria Mildly elevated serum creatine and blood urea nitrogen	Persistent proteinuria Reduced glomerular filtration rate or creatine clearance rate Abnormal urinalysis
Other diagnostic tests		Renal ultrasound shows reduced kidney mass

P450 (CYP), *N*-acetyltransferase, glutathione transferase, renal peptidases, and other enzymes responsible for the degradation and activation of selected endogenous and exogenous substances have been identified in the kidney. The CYP enzymes in the kidneys are as active as that in the liver, when corrected for organ mass. In vitro studies have demonstrated impaired function of CYP3A4 and CYP2C9, whereas CYP1A2, CYP2C19, and CYP2D6 are not affected. These data are supported by recent clinical trials in patients with ESRD receiving hemodialysis, where hepatic CYP3A activity was reported to be reduced by 28% from values observed in age-matched controls; partial correction was noted following the hemodialysis procedure.[15,16] See Chapter 57 for a more detailed discussion.

QUALITATIVE AND SEMIQUANTITATIVE INDICES OF KIDNEY FUNCTION

Patients who develop CKD remain relatively asymptomatic until impairment has progressed to the point that systemic manifestations and/or secondary complications become evident (Table 50–2). As renal function declines, patients may develop de novo or experience an exacerbation of hypertension, edema, electrolyte abnormalities, anemia, or other complications (see Chapters 52 and 53). The National Kidney Foundation (NKF) currently recommends that all patients with CKD, and those at increased risk for CKD, undergo at least yearly a comprehensive laboratory assessment composed of (a) serum creatinine to estimate GFR; (b) albumin-to-creatinine ratio in a spot urine specimen; (c) examination of urine sediment for red blood cell and white blood cell counts; (d) renal ultrasonography; (e) serum electrolytes, including sodium, potassium, chloride, and bicarbonate; (f) urine pH; and (g) urine-specific gravity.[17] The roles of each of these indices in the identification and monitoring of CKD are discussed in detail below.

LABORATORY PROCEDURES TO DETECT THE PRESENCE OF KIDNEY DISEASE

Urinalysis is an important tool for detecting and differentiating various aspects of kidney disease, which often goes unnoticed as the result of its asymptomatic presentation. It can be used to detect and monitor the progression of diseases such as diabetes mellitus, glomerulonephritis, and chronic urinary tract infections.[17–19] A typical urinalysis provides information about physical and chemical composition, most of which can be completed quickly and inexpensively by visual observation (volume and color) and dipstick testing. Microscopic urinalysis requires use of a light microscope to determine cellular content, as described below.

Chemical Analysis of Urine

pH The normal urine pH typically ranges from 4.5 to 7.8; an elevation above this may suggest the presence of urea-splitting bacteria. In patients with renal tubular acidosis, urine pH is usually >5.5 because of impaired hydrogen ion secretion in the distal tubule or collecting duct.

Glucose Glucose is usually not present in the urine because the kidney normally completely reabsorbs all the glucose filtered at the glomerulus. When a patient's blood glucose concentration exceeds the maximum threshold for glucose reabsorption in the kidney (~180 mg/dL [~10 mmol/L]), glucosuria will be present. Routine assessment of glucosuria has been replaced by newer methods of direct blood glucose measurements. Urine glucose testing is now used mainly as a screening tool for the detection of diabetes.

Ketones Acetoacetate and acetone normally are not found in the urine; they are, however, excreted in patients with diabetic ketoacidosis. They are also present under conditions of fasting or starvation. Typically, values of acetone excretion are reported as small (<20 mg/dL [<3.4 mmol/L]), moderate (30–40 mg/dL [5.2–6.9 mmol/L]), and large (>80 mg/dL [>13.8 mmol/L]).

Nitrite Nitrite usually is not present in urine. The presence of nitrite is most commonly the result of conversion from urinary nitrate by bacteria in the urine. The presence of nitrite thus suggests that the patient has a urinary tract infection, commonly caused by gram-negative rods such as *Escherichia coli.* Although false-positive results are very rare, false-negative results are more common and may be caused by a lack of dietary nitrate, reduced urine nitrate concentration as a consequence of diuresis, or infections caused by bacteria, such as enterococci and *Acinetobacter,* which do not reduce nitrate, and pseudomonads, which convert nitrate to nitrogen gas.

Leukocyte Esterase Leukocyte esterase is released from lysed granulocytes in the urine; its presence is suggestive of urinary tract infection. False-positive tests can result from delayed processing of the urine sample, contamination of the sample with vaginal secretions (e.g., blood or heavy mucus discharge), or by *Trichomonas* infection (e.g., trichomoniasis). False-negative tests can be produced by the presence of high levels of protein or ascorbic acid.

Heme The heme test indicates the presence of hemoglobin or myoglobin in the urine. A positive test without the presence of red blood cells suggests either red cell hemolysis or rhabdomyolysis.

Protein or Albumin Persistent proteinuria or albuminuria, that is, observation of its presence on at least three occasions over a period of 3 to 6 months, is now considered the principal marker of kidney damage.[16,17]

❷ Evaluation of urinary protein or albumin is now a standard tool used to characterize the severity of CKD and to monitor the rate of disease progression or regression. Under normal conditions, plasma proteins remain in the glomerular capillaries as blood perfuses the kidney and thus do not cross the glomerular basement membrane or enter the urinary space. Some of these proteins, such as albumin and globulins, are not filtered by the glomerulus as a result of charge and size selectivity (>40 kDa). Smaller proteins (<20 kDa) pass across the glomerular basement membrane but are readily reabsorbed in the proximal tubule. Most healthy individuals excrete between 30 and 150 mg/day of total protein consisting of approximately 30 mg of albumin. The remainder of the protein in the urine is secreted by the

tubules (Tamm-Horsfall, immunoglobulin A, and urokinase) or comprised of smaller proteins, such as β_2-microglobulin, apoproteins, enzymes, and peptide hormones. Increased excretion of these low molecular weight proteins in the urine is considered a sensitive marker of tubulointerstitial disease.

Historically, the sulfosalicylic acid test was used as a crude measure of proteinuria. This test is performed by adding sulfosalicylic acid to urine and then visually comparing this admixture with a tube of untreated urine; the presence of turbidity indicates the qualitative presence of proteinuria. Dipstick tests are now the most common means to determine in a semiquantitative fashion a patient's daily urine protein or albumin excretion. False-positive results can occur in the presence of alkaline urine (pH >7.5), when the dipstick is immersed too long, in those with highly concentrated urine, in the presence of drugs such as penicillin, sulfonamides, and tolbutamide, as well as blood, pus, semen, and vaginal secretions. False-negative results occur with dilute urine (specific gravity <1.015) and when proteinuria is caused by nonalbumin or low molecular weight proteins such as heavy or light chains or Bence Jones proteins. The results of these dipstick tests are graded as negative (<10 mg/dL [<100 mg/L]), trace (10–20 mg/dL [100–200 mg/L]), 1+ (30 mg/dL [300 mg/L]), 2+ (100 mg/dL [1,000 mg/L]), 3+ (300 mg/dL [3,000 mg/L]), or 4+ (>1,000 mg/dL [>10,000 mg/L]). Portable desktop analyzers such as the Chemstrip 101 Urine Analyzer (Roche Diagnostics) and Clinitek 50 Urine Chemistry Analyzer (Bayer Corporation) can also be used as an alternative to visual urinalysis test strip evaluation.

3 Because most dipstick methods are not specific for albumin, test strips that are specific for low levels of albuminuria (30–300 mg/day) should be employed. Microalbuminuria test strips, such as the Chemstrip Micral-Test II (Roche Diagnostics), when dipped into a urine sample assume a color ranging from white (0 mg/L) to red (100 mg/L), depending on the amount of albumin present in the sample. In patients with a positive protein or albumin dipstick test, a 24-hour urine collection with measurement of albumin excretion can be used to further define the degree of albuminuria. However, this method requires a high degree of patient compliance and is being replaced by a similarly accurate but less cumbersome technique: calculation of the ratio of protein or albumin (in milligrams) to creatinine (in grams [or millimoles]) obtained from an untimed (spot) urine specimen. The normal ratio is <30 mg albumin or <200 mg protein per gram of creatinine (<3.4 mg albumin or <22.6 mg protein per millimole of creatinine) in the urine, with values between 30 and 300 mg of albumin per gram of creatinine (3.4–22.6 mg of albumin per millimole of creatinine) considered to be in the microalbuminuria range.[17] Positive test results should be repeated, particularly in patients without an underlying cause for renal disease, such as diabetes or hypertension. Monitoring of the degree of glomerular injury in patients with CKD should use the albumin-to-creatinine ratio, whereas for patients with clinical proteinuria, that is, excretion of >500 mg per day or an albumin-to-creatinine ratio >500 mg/g (>56.6 mg/mmol), the protein-to-creatinine ratio can be used.

CLINICAL CONTROVERSY

In the past, measurement of the urinary protein excretion rate was accomplished using a 24-hour urine collection in patients who were at risk for CKD. However, many now advocate the use of an untimed "spot" urine sample with either an albumin-specific dipstick or measurement of the albumin-to-creatinine ratio.

Specific Gravity Specific gravity is a measure of urine weight relative to water (1.00) that is performed using a refractometer. Thus, specific gravity is dependent on water intake and urine-concentrating ability. Normal values range from 1.003 to 1.030. Osmolality, which is a measure of the number of solute particles in the urine, is a more accurate measure of the kidney's ability to make a concentrated urine. Generally, the two values correlate; however, when large quantities of heavier molecules, such as glucose, are in the urine, the specific gravity may be elevated relative to the osmolality. These tests are used in the assessment of urine-concentrating ability and are most informative when interpreted along with the hydration status of the patient and plasma osmolality.

Microscopic Analysis of Urine Formed elements that may be detected in the urine include erythrocytes and leukocytes, casts, and crystals. An important consideration in the assessment of hematuria is whether the cells are of renal origin. More than two cells per high-power field is abnormal, and the presence of dysmorphic cells suggests renal parenchymal origin because of damage as they pass through the glomerulus or during exposure to the varying osmotic environments of the tubular lumen. White blood cells may be present in the urine in association with infection or inflammatory conditions, such as interstitial nephritis. More than one cell per high-power field is usually considered abnormal. Contamination of the sample should also be considered when there are many cells; such contamination may be the result of menses or of inadequate sample collection. Casts are cylindrical forms composed of protein, with or without cells that take the shape of the collecting tubules, where they are formed. Casts without cells are labeled *hyaline casts* and consist of the Tamm-Horsfall mucoprotein, secreted by the renal tubules. They are nonspecific and may appear in concentrated urine. In the presence of red or white blood cells, casts may be formed that include the cells, indicating that the cells were of renal origin. Solubility of the Tamm-Horsfall protein is increased as urine pH rises; therefore, sample collection for casts should occur with the first morning void when the urine is most acidic. Otherwise, casts may dissolve and elude detection.

A variety of crystals may be present in the urine, including uric acid, calcium oxalate, calcium phosphate, calcium magnesium ammonium pyrophosphate, and cystine. Many of these have a unique crystalline form, which permits them to be identified with microscopy.

Serum or Blood Urea Nitrogen

Amino acids metabolized to ammonia are subsequently converted in the liver to urea, the production of which is dependent on protein availability (diet) and hepatic function. Urea undergoes glomerular filtration followed by reabsorption of up to 50% of the filtered load in the proximal tubule. The reabsorption rate of urea is mainly dependent on the reabsorption of water. The excretion of urea may therefore be decreased under conditions that necessitate water conservation, such as dehydration, although the GFR may be normal or only slightly reduced. This condition is evident when a patient exhibits prerenal azotemia, or an increase of the blood urea nitrogen to a greater extent than the serum creatinine. The normal blood urea nitrogen (BUN)-to-creatinine ratio is 10 to 15:1 using conventional units (1:25 to 1:16 using SI units), and an elevated ratio (decreased ratio using SI units) is suggestive of a decreased effective circulating volume, which stimulates increased water and hence urea reabsorption. Creatinine is not reabsorbed to any significant extent by the kidneys. Despite these limitations, BUN is usually used in combination with the serum creatinine concentration as a simple screening test for the detection of renal dysfunction.

Serum Creatinine

Creatinine is the primary standard endogenous biomarker used for the detection of kidney disease. The third National Health and Nutrition Examination Survey (NHANES III) revealed a mean serum creatinine of 0.96 mg/dL (85 μmol/L) in women and 1.16 mg/dL (103 μmol/L) in men in the United States.[20] Values were lower among Mexican Americans and higher among non-Hispanic blacks. For all groups, the serum creatinine increased with age. The report also noted that among community-dwelling adults, 10.9 million have a serum creatinine greater than 1.5 mg/dL (133 μmol/L), 3 million have a serum creatinine greater than 1.7 mg/dL (150 μmol/L), and 0.8 million have a serum creatinine greater than 2 mg/dL (177 μmol/L). Although the serum creatinine concentration alone is not an optimal measure of kidney function, it is often used as a marker for referral to a nephrologist. There is presently no accepted single standard for an "abnormal" serum creatinine level, as it is dependent on gender, race, age, and lean body mass.

The concentration of creatinine in serum is a function of creatinine production and renal excretion. Creatinine is a product of creatine metabolism from muscle; therefore, its production is directly dependent on muscle mass. At steady state, the "normal" serum creatinine concentration range is 0.5 to 1.5 mg/dL (44–133 μmol/L) for men and women. Creatinine is eliminated primarily by glomerular filtration, and as GFR declines, the serum creatinine concentration rises (Fig. 50–2).

Several methods are used to determine serum creatinine concentration, most of which use the nonspecific Jaffe reaction, a colorimetric method based on the reaction of creatinine with alkaline picrate. This nonspecific method also reacts with noncreatinine chromogens in the serum, which may result in a falsely increased serum creatinine concentration.[18] Noncreatinine chromogens are not present in the urine in sufficient quantities to interfere with the urinary creatinine measurement, because the concentration of creatinine in urine is several-fold greater than the serum concentration. The impact of this interference is seen with the creatinine clearance (CL_{cr}) calculation:

$$CL_{cr} = (U_{cr} \times V)/(S_{cr} \times t)$$

where U_{cr} = urine creatinine concentration, V = urine volume, S_{cr} = serum creatinine concentration, and t = duration of the urine collection.

This "normal" interference results in an increase in the serum creatinine concentration of ~10%; therefore, the measured creatinine clearance would underestimate the true GFR by 10%. In subjects with normal renal function, this tends to counterbalance the effect of the contribution of tubular secretion of creatinine, which increases urine creatinine by nearly 10%. Thus, CL_{cr} has been proposed to serve as a good measure of GFR in subjects with normal renal function. However, this false increase in serum creatinine becomes less noticeable as the true creatinine concentration rises, due to the increasing contribution of tubular secretion to the renal clearance of creatinine.[21] This becomes significant when kidney function is reduced to less than 50% of normal.

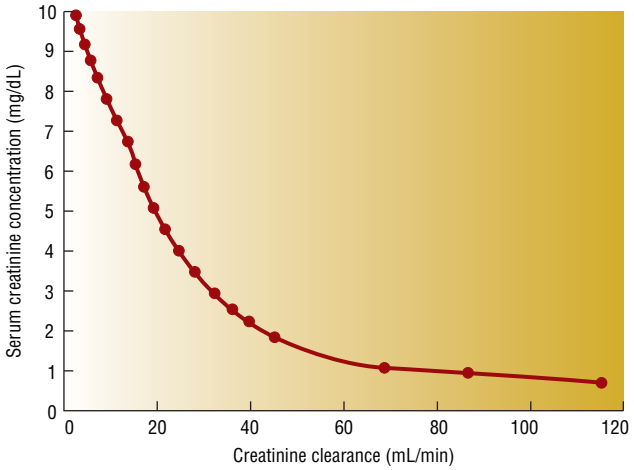

FIGURE 50-2. Relationship between serum creatinine and creatinine clearance.

TABLE 50-3 Factors that may alter Creatinine Clearance Determinations

Analytical	Physiologic
Acetoacetate	Age, weight, gender
Ascorbic acid	Diet
Cephalosporins (cephalothin, cefazolin, cephalexin, cefoxitin, cefaclor, cephradine)	Diurnal variation
Clavulonic acid	Cimetidine
Dobutamine	Trimethoprim
Dopamine	Probenecid
5-flucytosine	Exercise
Fructose	
Glucose	
Protein	
Pyruvate	
Uric acid	

Diabetic ketoacidosis may produce increased concentrations of acetoacetate, which serves as a chromophore in the Jaffe reaction, thereby increasing the serum creatinine concentration. Other substances that react with this procedure in the serum are glucose, protein, pyruvate, fructose, uric acid, and ascorbic acid (Table 50–3). In addition, some antibiotics are associated with a false increase in serum creatinine concentration, including cephalothin, cefazolin, cephalexin, cefoxitin, cefaclor, cephradine, and clavulanic acid.[22,23] Other agents, such as the fluoroquinolones (ciprofloxacin, fleroxacin, lomefloxacin, ofloxacin, levofloxacin, sparfloxacin, and temafloxacin), do not produce a false elevation in serum creatinine.[24] The degree of interference is dependent on the serum concentration of the antibiotic, so blood samples for creatinine should be obtained when the antibiotic concentration is lowest (at the end of a dosing interval). These interferences are not observed when the serum creatinine is measured using an enzymatic technique. The antifungal agent 5-flucytosine causes an increase in serum creatinine when measured using the Ektachem (Eastman Kodak) enzymatic system, but it does not interact with the Jaffé method.[25] Daly et al.[26] reported a false-negative effect of dobutamine and dopamine on the serum creatinine value when measured using the Ektachem system. The interference is concentration dependent and results in a 10% to 100% decrease in serum creatinine concentration. The authors hypothesized that both drugs compete with the chromogenic dye for oxidation by hydrogen peroxide in a concentration-dependent manner. The problem is most evident when blood samples are contaminated with residual IV solution containing the interfering drug. These differences emphasize the need to standardize a method within the clinic setting and require the clinician to be aware of the methods employed in the laboratory for the determination of creatinine concentrations.

Other compounds are known to interfere with serum creatinine concentration by inhibiting the active tubular secretion of creatinine. Among these are cimetidine and trimethoprim, which compete for creatinine secretion at the cationic transport system in a dose-dependent fashion. Cimetidine, given as a single 400 mg

dose, can result in a reduction of the CL_{cr}-to-inulin clearance ratio from 1.30 to 1.03, without a change in inulin clearance. Ranitidine, an H_2-receptor antagonist similar to cimetidine, however, does not have a similar effect on creatinine secretion following single doses of 300 to 1,200 mg.[27]

Serum creatinine concentration is dependent on the "input" function, or formation rate, and "output" function, or elimination rate. Its formation rate depends on the zero-order production from creatine metabolism, as well as input from other sources, such as dietary intake. Creatine metabolism is directly proportional to muscle mass; therefore, individuals with more muscle mass have a higher serum creatinine concentration at any given degree of kidney function than those with less muscle mass. Strenuous exercise is associated with an increase of ~10% in the level of serum creatinine. In contrast, cachectic patients, as the result of minimal muscle mass, will have very low serum creatinine concentrations, as do those with spinal cord injuries.[28] Elderly patients and those with poor nutrition may also have low serum creatinine concentrations (<1.0 mg/dL [88 μmol/L]) secondary to decreased muscle mass. Dietary intake of creatine also influences serum creatinine concentration. During the cooking of meat, some creatine is converted to creatinine, which is rapidly absorbed following ingestion.

Serum creatinine concentrations may rise as much as 50% within 2 hours of a meat meal and remain elevated for as long as 8 to 24 hours.[29] Ingestion of creatine as an ergogenic dietary supplement is currently popular. There are conflicting reports as to the effect of creatine ingestion on serum creatinine concentration. Poortsmans and Francaux[30] evaluated a short-term regimen of 20 g creatine per day for 5 days in healthy subjects and reported no significant change in serum creatinine concentration, creatinine excretion rate, or creatinine clearance. Robinson et al.,[31] however, reported a 25% to 40% increase in serum creatinine concentration after ingestion of 20 g creatine per day for either 5 days or 8 weeks. The renal excretion rate of creatinine was not measured. The issue of whether creatine ingestion adversely affects kidney function was studied by Edmunds et al.[32] They noted that creatine supplementation led to an increase in renal disease progression in a rat model for renal cystic disease, suggesting that creatine supplementation may be a risk factor in patients with preexisting renal disease. These conditions present a problem only when a single serum creatinine concentration is used to represent the entire 24-hour collection period, which is usually the case. An alternative is to obtain multiple samples and calculate the area under the serum concentration time curve and divide this by the collection time interval to obtain the average plasma creatinine concentration. This is rarely done in clinical practice, but it points out the need to question patients regarding dietary intake for the 24 hours preceding the measurement of CL_{cr}.

Diurnal variation in serum creatinine concentration may also affect the accuracy of the CL_{cr} determination. Although the fluctuation is minimal, the observed peak plasma creatinine concentration generally occurs at approximately 7:00 PM, whereas the nadir is in the morning. To minimize this effect, the CL_{cr} is usually performed over a 24-hour period with the plasma creatinine obtained in the morning, as long as the patient has stable kidney function. Collection of urine remains a limiting factor in the 24-hour CL_{cr} because of incomplete collections and interconversion between creatinine and creatine that can occur if the urine is not maintained at a pH <6.

Serum and Urinary Cystatin C

Cystatin C is a 132 amino acid (13.3 kDa) cysteine protease inhibitor produced by all nucleated cells of the body that is considered a biomarker of renal function. It is freely filtered at the glomerulus and undergoes both reabsorption and catabolism in the proximal tubule. The renal handling of this biomarker is distinctly different from creatinine and exogenous GFR markers, such as inulin, iohexol, and iothalamate. Originally introduced in Europe, it was recommended as a marker of kidney function because of findings that serum concentrations significantly correlated with GFR as well as serum creatinine. It was hypothesized that because cystatin C production was not limited to muscle mass, it would provide a more reliable estimate of renal function than creatinine. However, it has now been shown that serum cystatin C concentrations can be altered by many factors other than kidney function, such as age, nutritional status, gender, weight, height, cigarette smoking, serum C-reactive protein levels, steroid therapy, and rheumatoid arthritis.[33–35] Recent studies have reported that it may be a more sensitive index of kidney disease or acute injury compared with serum creatinine. Comparison of ^{125}I-iothalamate with serum creatinine and cystatin C showed that the serum creatinine began to increase when the GFR was <75 mL/min/1.73 m^2 (0.72 mL/s/m^2), whereas cystatin C concentrations began to rise when the GFR dropped below 88 mL/min/1.73 m^2 (0.85 mL/s/m^2).[33] The recent development of an automated immunoassay technique has resulted in the development of suggested reference ranges of 0.70 to 1.38 mg/L in children older than 1 year of age and 0.55 to 1.37 mg/L in adults. However, Keevil et al.[36] reported that serum cystatin C had greater intraindividual variability than serum creatinine in healthy individuals, which may limit its use in longitudinal evaluations of renal function.

The utility of cystatin C as a quantitative measure of GFR is still largely unkown. In a 4-year longitudinal study in 30 Pima Indians without CKD, the reciprocal cystatin C index (100/cystatin C) was shown to be a better predictor of declining GFR than was reciprocal serum creatinine, estimated GFR, or CL_{cr}.[37] However in patients being treated for malignant disease, Page et al.[38] reported increased cystatin C concentrations that were independent of CL_{cr}. Cystatin C concentrations were also noted to be independent of GFR and weakly associated with measured creatinine clearance, in pediatric and adult renal transplant recipients, possibly due to the formation of cystatin–immunoglobulin complexes or reduced tubular catabolism.[39,40] Two additional studies have shown a strong association between serum cystatin C and cardiovascular disease in elderly and non-CKD patients, suggesting that it may provide useful prognostic information in some populations.[41,42]

In addition to longitudinal monitoring of serum cystatin C values, at least five equations have been proposed to determine estimated GFR (eGFR) using serum cystatin C (CysC) and demographic variables including lean body mass (LM), age, gender, race, and serum creatinine (S_{cr}):[43–46]

$$\text{eGFR (mL/min)} = 77.24 \times (\text{CysC in mg/L})^{-1.2623}$$

$$\text{Log}_{10}\text{eGFR (mL/min)} = 2.222 + \left(-0.802 \times \sqrt{\text{CysC in } \frac{\text{mg}}{\text{L}}}\right) + (0.009876 \times \text{LM})$$

$$\text{eGFR (mL/min/1.73 m}^2) = 127.7 \times (\text{CysC in mg/L})^{-1.17} \times (\text{age in years})^{-0.13} \times 0.91 \text{ [if female]} \times 1.06 \text{ [if black]}$$

$$\text{eGFR (mL/min/1.73 m}^2) = 76.7 \times (\text{CysC in mg/L})^{-1.19}$$

$$\text{eGFR (mL/min/1.73 m}^2) = 177.6 \times (S_{cr} \text{ in mg/dL})^{-0.65} \times (\text{CysC in mg/L})^{-0.57} \times (\text{age in years})^{-0.20} \times 0.82 \text{ [if female]} \times 1.11 \text{ [if black]}$$

Conversion from eGFR conventional units of mL/min/1.73 m^2 to eGFR SI units of mL/s/m^2 requires multiplication by 0.00963; conversion from eGFR conventional units of mL/min to eGFR SI units of mL/s requires multiplication by 0.0167. Serum creatinine in μmol/L can be converted to mg/dL by multiplication using 0.0113 as the conversion factor.

Recent studies by MacDonald et al.[43] and Vupputuri et al.[46] reported that body weight is a significant covariate in GFR determination using cystatin C. Using GFR measured as plasma inulin clearance, lean body mass accounted for at least 16.3% of the variance in GFR values obtained using cystatin C (P <0.001). When using a cystatin C-based estimate of GFR, which incorporates the CysC, age, race, and gender, a higher prevalence of CKD was reported in obese patients when compared with the MDRD4 equation.[46] Thus, a rigorous evaluation of the impact of body composition and obesity on GFR estimates using cystatin C is needed.

Alternative Methodologies

Urinary biomarkers such as KIM-1, NGAL, and cystatin C have shown promise in detecting early kidney injury.[47] Because it is normally reabsorbed and catabolized in the renal proximal tubule, it is hypothesized that tubular damage would lead to increased urinary excretion of cystatin C. Koyner et al.[48] showed that postoperative cardiac surgery patients with early elevated urinary cystatin C concentrations (corrected for urinary creatinine) had the highest prevalence of developing acute kidney injury (AKI). Here, plasma creatinine concentrations did not peak until 48 hours after admission to the intensive care unit, suggesting that urinary biomarkers such as cystatin C may be beneficial in early diagnosis of AKI. Use of cystatin C as a quantitative measure of GFR requires further study and may yield useful information for comprehensive evaluations of health and cardiovascular status, including detection of acute and chronic changes in kidney function.

Beta-trace protein (BTP) has recently been proposed as a new alternate endogenous marker of GFR.[49–51] Similar to cystatin C, it is a low molecular weight glycoprotein (168 amino acids) that is filtered through the glomerular basement membrane and reabsorbed in the renal proximal tubule. Elevated concentrations of BTP in serum have been reported in patients with CKD,[52] kidney transplant recipients,[53] and children.[54] Equations to estimate GFR that incorporate BTP concentrations in adults and pediatric populations are currently being evaluated.[55]

MEASUREMENT OF KIDNEY FUNCTION

The gold standard quantitative index of kidney function is a measured GFR. A variety of methods may be used to measure and estimate kidney function in the acute care and ambulatory settings. Estimation of GFR is important for early recognition and monitoring of patients with CKD. Estimation of CL_{cr} is important as a guide for drug dose adjustment in the presence of renal impairment.

It is important to recognize conditions that may alter renal function independent of underlying renal pathology. For example, protein intake, such as oral protein loading or an infusion of amino acid solution, may increase GFR.[10] As a result, inter- and intrasubject variability must be considered when it is used as a longitudinal marker of renal function. Dietary protein intake has been demonstrated to correlate with GFR in healthy subjects. Brändle et al.[56] evaluated renal function in four groups of healthy volunteers, each ingesting a diet controlled for protein over a 4-month period. The GFR was nonlinearly related to urine nitrogen excretion, with an observed maximum of 181.7 mL/min (3.03 mL/s) at a urinary nitrogen excretion rate of 20 g/day (1.43 mol/d), or 125 g/day protein intake. Subjects who are vegetarian have a lower GFR than individuals who consume a similar caloric but normal protein content diet because of their reduced dietary protein intake. When challenged with a protein load, the vegetarian subjects are able to increase their GFR to the "normal" range.[10] Findings from the Nurses' Health Study[57] indicate that longitudinal changes in GFR are independent of the source of protein (nondairy animal, dairy, or vegetable) in women with normal renal function. However, women with mild renal insufficiency (GFR 71 ± 7 mL/min [1.18 ± 0.12 mL/s]) who consumed the highest amount of protein (93 g/day) had a threefold greater risk of a ≥5 mL/min (≥0.08 mL/s) decline in GFR compared with the lowest protein group (60 g/day); rates of decline were highest in those consuming nondairy animal protein. The increased GFR following a protein load is the result of renal vasodilation accompanied by an increased renal plasma flow. The exact mechanism of the renal response to protein is unknown but may be related to extrarenal factors such as glucagon, prostaglandins, and angiotensin II, or to intrarenal mechanisms, such as tubular transport and tubuloglomerular feedback.[58,59] Despite the evidence of a "renal reserve," standardized evaluation techniques have not been developed. Therefore, assessment of the standard GFR measurement technique must consider the dietary protein status of the patient at the time of the study.

CLINICAL CONTROVERSY

The estimation of creatinine clearance in elderly patients with low serum creatinine values is controversial. Some clinicians advocate correction of serum creatinine to 1 mg/dL to account for reduced muscle mass. The impact of this correction factor on GFR estimates using MDRD4 or other equations has yet to be evaluated in this population.

MEASUREMENT OF THE GLOMERULAR FILTRATION RATE

4 A measured GFR remains the single best index of functioning renal mass. As renal mass declines in the presence of age-related loss of nephrons or coexisting disease states such as hypertension and diabetes, there is a progressive decline in GFR. The rate of decline in GFR can be used to predict the time to onset of stage 5 CKD, as well as the risk of complications of CKD. Accurate measurement of GFR in clinical practice is a critical variable for the individualization of the dosage regimens of renally excreted medications so as to maximize their therapeutic efficacy and avoid potential toxicity.

The GFR is expressed as the volume of plasma filtered across the glomerulus per unit time, based on total renal blood flow and capillary hemodynamics. The normal values for GFR are 127 ± 20 mL/min/1.73 m^2 (1.22 ± 0.19 mL/s/m^2) and 118 ± 20 mL/min/1.73 m^2 (1.14 ± 0.19 mL/s/m^2) in healthy men and women, respectively. For example, if the normal renal blood flow was ~1 L/min/1.73 m^2 (0.01 mL/s/m^2), plasma volume was 60% of blood volume, and filtration fraction across the glomerulus was 20%, then the normal GFR would be ~120 mL/min/1.73 m^2 (1.16 mL/s/m^2).

Because GFR cannot be measured directly in humans, clearance methods that use substances that are freely filtered without additional clearance because of tubular secretion or reduction as the result of reabsorption are required. Additionally, the substance should not be susceptible to metabolism within renal tissues and should not alter renal function. Given these conditions, the GFR is equivalent to the renal clearance of the solute marker:

$$\text{GFR} = \text{renal CL} = (A_e)/\text{AUC}_{0-t}$$

where renal CL is renal clearance of the marker, A_e is the amount of marker excreted in the urine in a specified period of time, t, and AUC_{0-t} is the area under the plasma concentration-versus-time curve of the marker.

TABLE 50-4 Sensitivity and Clinical Utility of Renal Function Tests

	Accuracy	Clinical Utility	Cost
Inulin clearance	++++	+	$$$$
Radiolabeled markers	+++	+	$$$
Nonisotopic contrast agents	+++	++	$$$
Creatinine clearance	++	+++	$$
Serum creatinine	+	++++	$

+ = least acceptable, ++ = adequate, +++ = better, ++++ = best.

Under steady-state conditions, for example, during a continuous infusion of the marker, the expression simplifies to

$$\text{GFR} = \text{renal CL} = (A_e)/(C_{ss} \times t)$$

where C_{ss} is the steady-state plasma concentration of the marker achieved during continuous infusion. The continuous infusion method can also be employed without urine collection, where plasma clearance is calculated as CL = infusion rate/C_{ss}. Requirements of this method include steady-state plasma concentrations and accurate measurement of infusate concentrations. Plasma clearance can also be determined following a single-dose IV injection with multiple samplings of blood to estimate area under the curve ($AUC_{0-\infty}$). Here, clearance is calculated as CL = dose/AUC. These plasma clearance methods commonly yield clearance values 10% to 15% higher than urine collection methods.[60,61]

5 Several markers have been used for the measurement of GFR, including both exogenous and endogenous compounds. Those administered as exogenous agents, such as inulin, iothalamate, iohexol, and radioisotopes, require specialized administration techniques and detection methods for the quantification of function, but they generally provide a more accurate measure of GFR. Methods that employ endogenous compounds, such as creatinine, require less technical expertise but produce results with greater variability. The marker of choice depends on the purpose and cost of the test (e.g., ^{125}I-iothalamate costs $2,000 per vial [Glofil-125, QOL Medical]); research protocols will generally use a more accurate test than one used in the clinical setting (Table 50–4).

Inulin Clearance

Inulin is a large fructose polysaccharide (5,200 Da) obtained from the Jerusalem artichoke, dahlia, and chicory plants. It is not bound to plasma proteins, is freely filtered at the glomerulus, is not secreted or reabsorbed, and is not metabolized by the kidney. The volume of distribution of inulin approximates extracellular volume, or 20% of ideal body weight. Because it is eliminated by glomerular filtration, its elimination half-life is dependent on renal function and is ~1.3 hours in subjects with normal renal function. Measurement of plasma and urine inulin concentrations can be performed using high-performance liquid chromatography.[62] Sinistrin, another polyfructosan, has similar characteristics to inulin; it is filtered at the glomerulus and not secreted or reabsorbed to any significant extent. It is a naturally occurring substance derived from the root of the North African vegetable red squill, *Urginea maritime,* which has a much higher degree of water solubility than inulin. Assay methods for sinistrin have been described using enzymatic procedures, as well as high-performance liquid chromatography with electrochemical detection.[63]

Iothalamate Clearance

Alternatives have been sought for inulin as a marker for GFR because of the problems of availability, high cost, sample preparation, and assay variability. Iothalamate is an iodine-containing radiocontrast agent that is available in both radiolabeled (^{125}I) and nonradiolabeled forms. This agent is handled in a manner similar to that of inulin; it is freely filtered at the glomerulus and does not undergo substantial tubular secretion or reabsorption. The nonradiolabeled form is most widely used to measure GFR in ambulatory and research settings and can safely be administered by IV bolus, continuous infusion, or subcutaneous injection.[64] Plasma and urine iothalamate concentrations can be measured using high-performance liquid chromatography.[65] A reported slight positive bias of ~10 mL/min (0.17 mL/s) suggests that there is some degree of nonrenal clearance of this agent. However, plasma iothalamate clearance methods that do not require urine collections have been shown to be highly correlated with iothalamate renal clearance, making them particularly well suited for longitudinal evaluations of renal function.[66]

Iohexol

Iohexol, a nonionic, low osmolar, iodinated contrast agent, has also been used for the determination of GFR. It is eliminated almost entirely by glomerular filtration, and plasma and renal clearance values are similar to observations with other marker agents: strong correlations of 0.90 or greater and significant relationships such as $CL_{iohexol} = 0.90\ CL_{iothalamate} + 6.8$ mL/min have been reported.[67–69] These data support iohexol as a suitable alternative marker for the measurement of GFR. One key advantage of this agent is that a single plasma sample can be used to quantify iohexol clearance, provided sufficient time has elapsed since injection. For patients with a reduced GFR, more time must be allotted—more than 24 hours if the estimated GFR is less than 20 mL/min (0.33 mL/s).[67]

Radiolabeled Markers

The GFR has also been quantified using radiolabeled markers, such as ^{125}I-iothalamate (614 Da, radioactive half-life of 60 days), ^{99m}Tc-diethylenetriamine pentaacetic acid (^{99m}Tc-DPTA; 393 Da, radioactive half-life of 6.03 hours), and ^{51}Cr-ethylenediaminetetraacetic acid (^{51}Cr-EDTA; 292 Da, radioactive half-life of 27 days).[70] These relatively small molecules are minimally bound to plasma proteins and do not undergo tubular secretion or reabsorption to any significant degree. ^{125}I-iothalamate and ^{99m}Tc-DPTA are used in the United States, whereas ^{51}Cr-EDTA is used extensively in Europe. The use of radiolabeled markers allows one to determine the individual contribution of each kidney to total renal function.[71] Various protocols exist for the administration of these markers and subsequent determination of GFR using either plasma or renal clearance calculation methods. The nonrenal clearance of these agents appears to be low (3–8 mL/min [0.05–0.13 mL/s]), suggesting that plasma clearance is an acceptable technique except in patients with severe renal insufficiency (GFR <30 mL/min [<0.50 mL/s]). Indeed, highly significant correlations between renal clearance among radiolabeled markers has been demonstrated.[72] Although total radioactive exposure to patients is usually minimal, use of one of these agents does require compliance with radiation safety committees and appropriate biohazard waste disposal.

Estimation of GFR

A series of equations for estimating GFR have been proposed over the past 10 years (Table 50–5). The most commonly used equations are those proposed by Levey and colleagues,[73–77] which have gained widespread support for the estimation of GFR as a tool for the identification and risk categorization of CKD in many patient populations. The initial equations were derived from multiple regression analysis of data obtained from the 1,628 patients enrolled in the Modification of Diet in Renal Disease Study (MDRD), where GFR was measured by renal clearance of ^{125}I-iothalamate. The first regression model yielded

TABLE 50-5 Equations for the Estimation of Creatinine Clearance and GFR in Adults with Stable Renal Function

Cockroft and Gault[89]	Men: $CL_{cr} = (140 - age)\ ABW/(S_{cr} \times 72)$ Women: $CL_{cr} \times 0.85$
Jelliffe[95]	Men: $CL_{cr} = (100/S_{cr}) - 12$ Women: $CL_{cr} = (80/S_{cr}) - 7$
Jelliffe[95]	Men: $CL_{cr} = 98 - [0.8\ (age - 20)]/S_{cr}$ Women: $CL_{cr} \times 0.9$
Mawer et al.[94]	Men: $IBW\ [29.3 - (0.203 \times age)]\ [1 - (0.03 \times S_{cr})/(14.4 \times S_{cr})$ Women: $IBW\ [25.3 - (0.175 \times age)]\ [1 - (0.03 \times S_{cr})]/(14.4 \times S_{cr})$
Hull et al.[96]	Men: $CL_{cr} = [(145 - age)/S_{cr}] - 3$ Women: $Cl_{cr} \times 0.85$
Levey et al. (MDRD6)[73]	$GFR = 170 \times (S_{cr})^{-0.999} \times [age]^{-0.176} \times [0.762$ if patient is female$] \times [1.180$ if patient is black$] \times [SUN]^{-0.170} \times [Alb]^{0.318}$
Levey et al. (MDRD4)[74]	$GFR = 186 \times (S_{cr})^{-1.154} \times [age]^{-0.203} \times [0.742$ if patient is female$] \times [1.210$ if patient is black$]$
Levey et al. (MDRD4-IDMS)[74]	$GFR = 175 \times (S_{cr})^{-1.154} \times [age]^{-0.203} \times [0.742$ if patient is female$] \times [1.210$ if patient is black$]$
Levey et al. (CKD-EPI)[81]	$GFR = 141 \times \min(S_{cr}/\kappa, 1)^{\alpha} \times \max(S_{cr}/\kappa, 1)^{-1.209} \times 0.993^{Age} \times 1.018$ [if female] $\times 1.159$ [if black]
Rule et al. (MCQ)[82]	$GFR = \exp\left[1.911 + \frac{5.249}{S_{cr}} - \frac{2.114}{S_{cr}^2} - 0.00686 \times Age - 0.205\ (\text{if female})\right]$

κ is 0.7 for women and 0.9 for men, α is −0.329 for women and −0.411 for men; min indicates the minimum of S_{cr}/κ or 1, and max indicates the maximum of S_{cr}/κ or 1. (If S_{cr} <0.8 mg/dL, use 0.8 for S_{cr}.)

ABW = actual body weight, Alb = serum albumin concentration (g/dL), CL_{cr} = creatinine clearance in mL/min, GFR = glomerular filtration rate, IBW = ideal body weight (kg), S_{cr} = serum or plasma creatinine (mg/dL), SUN = serum urea nitrogen concentration (mg/dL).

a six-variable Modification of Diet in Renal Disease Study (MDRD6) equation.[74,75] This new equation had a higher correlation coefficient (r^2 = 0.902) and thus provided a more precise estimate of GFR than measured CL_{cr} (r^2 = 0.866) or CL_{cr} estimated by the Cockcroft-Gault equation (r^2 = 0.842) in the MDRD population. A newer modified, four-variable version of the original MDRD equation (MDRD4), based on plasma creatinine, age, gender, and race, was shown to provide a similar estimate of GFR results compared with the six-variable equation predecessor[74] and has been subsequently updated based on the calibrated serum creatinine (IDMS) assay.[75] The MDRD4 equation is now recommended by the NKF and the National Kidney Disease Education Program (NKDEP) for calculating the estimated GFR (eGFR) in patients with a history of CKD risk factors and a GFR <60 mL/min/1.73 m² (<0.58 mL/s/m²). The performance of the MDRD equations has been assessed in a variety of patient populations with GFR <60 mL/min/1.73m² (<0.58 mL/s/m²), including those with diabetic nephropathy and renal transplant patients. However, the MDRD equations have been shown to be less accurate in healthy subjects, diabetic patients with normal GFR (88–182 mL/min/1.73 m² [0.85–1.75 mL/s/m²]), and healthy potential kidney donors.[76] In a small study of elderly subjects (age >68 years) with mild/moderate CKD (GFR 53 ± 18 mL/min/1.73 m² [0.51 ± 0.17 mL/s/m²]), the MDRD6 equation was slightly positively biased compared with the Cockcroft-Gault equation (8% vs. 10%), but precision was similar between methods relative to measured GFR.[77] Beddhu et al.[78] reported that the MDRD6 equation, like the Cockcroft-Gault equation, is dependent on creatinine production and is susceptible to bias in malnourished patients with ESRD. In patients with GFR values >60 mL/min/1.73 m² (>0.58 mL/s/m²), the values provided by the MDRD4 equation have been shown to be highly variable and less accurate then other traditional estimation methods, perhaps in part because the original study population consisted only of patients with low GFR values (<60 mL/min/1.73m² [<0.58 mL/s/m²]). The study also included few Asians, elderly patients, those with diabetes, or ill, hospitalized patients;[79] thus, the MDRD4 should be used with caution in children, the elderly, and those with extremes in muscle mass (cachectic and obese) until further performance data are available.

CLINICAL CONTROVERSY

Some practitioners are advocating the use of the MDRD4 equation in patients without CKD, although it appears to have a weaker correlation with GFR than the Cockcroft-Gault equation. Recent evidence suggests that the MDRD4 equation should be reserved for patients with a GFR <60 mL/min. The use of newer equations, such as the CKD-EPI, may have improved accuracy in patients with GFR >60 mL/min; however, further studies are required.

A single GFR equation may not be best suited for all populations, and choice of equation has been shown to affect CKD prevalence estimates.[80] This has led to a revitalized interest in the areas of nephrology, epidemiology, and development of new GFR equations over the past 5 years. The newest equations to be proposed for the estimation of GFR have been derived from wider CKD populations than the MDRD study and include the CKD-EPI[81] and Mayo Clinic Quadratic (MCQ) equations.[82] The CKD-EPI equation was developed from pooled study data involving 5,500 patients, with mean GFR values of 68 ± 40 mL/min/1.73 m² (0.65 ± 0.39 mL/s/m²) (range 2–190 mL/min/1.73m² [0.02–1.83 mL/s/m²]). It has been reported that the CKD-EPI equation is less biased (2.5 vs. 5.5 mL/min/1.73 m² [0.024 vs. 0.053 mL/s/m²]) but similarly imprecise compared with MDRD4. Rule et al.[82] developed the MCQ equation to estimate GFR from a population of CKD (n = 320) and healthy individuals (n = 580), using $1/S_{cr}$, $1/S_{cr}^2$, age, and gender as the covariates. Using the NHANES database, Snyder et al.[80] reported that MCQ GFR values resulted in 28% fewer patients being categorized as CKD stage 3 or 4 when compared with MDRD4. Thus, further evaluation of these newer GFR equations, including those incorporating "correction factors" for Japanese[83] and Chinese[84] populations, is needed. A variety of online resources that provide GFR calculators are available, such as the NKDEP website,[85] which provides GFR using the MDRD4 and MDRD4-IDMS equations. It should be noted that one must verify that a given equation is appropriate for the institutional creatinine reporting method.

The approach to standardize serum creatinine assays, and thereby improve the accuracy of eGFR results, has been implemented in most hospital clinical laboratories.[75] This IDMS assay calibration, called isotope dilution-mass spectrometry, is designed to reduce the interlaboratory variability in serum creatinine values. In settings using IDMS calibration, the revised MDRD-IDMS equation should be used based on the estimated 5% to 20% reduction in creatinine values. Recent recommendations from the NKDEP include reporting serum creatinine values in mg/dL to two decimal places (e.g., 0.93 mg/dL) and values in μmol/L to the nearest whole number (e.g., 84 μmol/L). This practice will likely reduce rounding errors that in the past contributed to bias between creatinine-based GFR or CL_{cr} estimates, but it does not improve GFR estimation in those without CKD. The impact of this new creatinine reporting approach on the accuracy of automated GFR results, calculated by a specified method, remains to be determined.

CLINICAL CONTROVERSY

Drug dose individualization is often required in patients with CKD. Approved drug labeling typically includes dose adjustment information based on the patient's estimated CL_{cr} using the Cockcroft-Gault method. Automated eGFR reporting by many hospital laboratories has now raised the question if the MDRD4 or any other GFR estimation equations should be used as a guide for drug dose adjustments.

Measured Creatinine Clearance

Although the measured (24-hour) CL_{cr} has served as the basis of developing CL_{cr} estimation equations in the past, it has limited clinical utility for estimation of GFR. Short-duration witnessed CL_{cr} correlates with iothalamate clearance performed using the single-injection technique. In a multicenter study[86] of 136 patients with type I diabetic nephropathy, the correlations of simultaneous CL_{cr}, Cockcroft-Gault CL_{cr}, and 24-hour CL_{cr} (compared with $CL_{iothalamate}$) were 0.81, 0.67, and 0.49, respectively, indicating increased variability with the 24-hour clearance determination. In a selected group of 110 patients, measurement of a 4-hour CL_{cr} during water diuresis provided the best estimate of the GFR as determined by the $CL_{iothalamate}$. Furthermore, the ratio of CL_{cr} to $CL_{iothalamate}$ did not appear to increase as the GFR decreased. These data suggest that a short collection period with a water diuresis may be the best method for estimation of GFR by creatinine clearance.

A limitation of using creatinine as a filtration marker is that it undergoes varying degrees of tubular secretion. Tubular secretion augments the filtered creatinine by ~10% in subjects with normal kidney function. If the nonspecific Jaffe reaction is used, which overestimates the serum creatinine concentration by ~10% because of the noncreatinine chromogens, then the creatinine clearance is a very good measure of GFR in patients with normal kidney function. Tubular secretion, however, increases to as much as 100% in patients with renal insufficiency.[21] As renal impairment develops, the remaining nephrons hypertrophy, and the degree of tubular secretion decreases less than the decrease in filtration. The result is an overestimation of creatinine clearance as a function of GFR assessed by inulin or iothalamate clearance. For example, Bauer et al.[21] reported that the CL_{cr}-to-CL_{inulin} ratio in subjects with mild impairment was 1.20; for moderate impairment, it was 1.87; and for severe impairment, it was 2.32. Thus, creatinine clearance is a poor indicator of GFR in patients with moderate to severe renal insufficiency.

Because cimetidine blocks the tubular secretion of creatinine, the potential role of several oral cimetidine regimens to improve the accuracy and precision of creatinine clearance as an indicator of GFR has been evaluated. The CL_{cr}-to-CL_{DPTA} ratio declined from 1.33 with placebo to 1.07 when 400 mg of cimetidine was administered four times daily for 2 days prior to and during the clearance determination.[87] Similar results were observed when a single 800 mg dose of cimetidine was given 1 hour prior to the simultaneous determination of CL_{cr} and $CL_{iothalamate}$; the ratio of CL_{cr} to $CL_{iothalamate}$ was reduced from a mean of 1.53 to 1.12.[88] Thus, a single oral dose of cimetidine 800 mg should provide adequate blockade of creatinine secretion to improve the accuracy of a creatinine clearance measurement as an eGFR in patients with stages 3 to 5 CKD.

Estimation of Creatinine Clearance

7 Many equations describing the mathematical relationships between various patient factors and CL_{cr} have been reported over the past 3 decades. Most equations incorporate factors such as age, gender, weight, and serum creatinine concentration, without the need for urine collection. The most widely used of these estimators is the Cockcroft-Gault equation,[89] which identified age and body mass as factors that significantly contribute to the estimate of CL_{cr}. This relationship was based on observations from 249 male patients with stable kidney function in whom the creatinine production rates were estimated. Estimated creatinine clearance, using the Cockcroft-Gault equation, remains the most common approach for stratifying patients in pharmacokinetic studies in clinical development and is reported most often in FDA-approved package inserts for new drug entities.[4]

The issue of which if any modified weight index should be used in the Cockcroft-Gault equation remains controversial, and approaches vary widely among clinical practitioners. For obese individuals, defined as those weighing >30% their ideal body weight (IBW), it is generally recommended that IBW be used in place of actual body weight (ABW)[90] in the Cockcroft-Gault equation, where

$$\text{IBW (kg, men)} = 50 + 2.3\ (\text{height in inches} > 60)$$

$$\text{IBW (kg, women)} = 45 + 2.3\ (\text{height in inches} > 60)$$

An alternative approach for estimating CL_{cr} (mL/min) in obese patients is the Salazar-Corcoran equation, which has been shown to be unbiased and superior to the Cockcroft-Gault equation in this population.[90,91] In the morbidly obese population, such as those with body mass index (BMI) ≥ 40 kg/m^2, use of lean body weight was recently reported to improve the accuracy of the Cockcroft-Gault equation in predicting 24-hour CL_{cr}.[92] Regardless of the approach used to estimate renal function in obese patients, it is imperative that drug therapy outcomes be monitored closely in this special population.

CLINICAL CONTROVERSY

The use of ideal or lean body weight for estimating CL_{cr} in obese patients is controversial. Some clinicians recommend using a weight adjustment in patients who are greater than 30% above IBW, such as using an adjusted body weight. However, some FDA package inserts provide renal dosing recommendations based on CL_{cr} calculations using IBW. Further research evaluating weight-based adjustments and drug pharmacokinetic outcomes is needed.

Luke et al.[93] evaluated the ability of the Cockcroft-Gault method and four other methods to predict CL_{cr}, with inulin clearance being considered the standard measure of GFR. The simultaneously determined inulin and creatinine clearances correlated best, $r^2 = 0.85$, and the CL_{cr} overestimated CL_{inulin} by ~15% due to tubular secretion of creatinine. For the five calculated clearances, Cockcroft-Gault and Mawer et al.[94] correlated the best with inulin clearance. The Cockcroft-Gault method showed a linear relationship with CL_{inulin} equal to 1.121 of CL_{cr} plus 20.6 mL/min (0.34 mL/s) ($r^2 = 0.66$), whereas for Mawer et al., the relationship was CL_{inulin} equal to 1.051 of CL_{cr} plus 18.3 mL/min (0.31 mL/s) ($r^2 = 0.66$). Other methods, such as Jelliffe[95] and Hull et al.,[96] consistently underestimated the CL_{cr}. As kidney function declined, there was an increase in the fraction of creatinine eliminated by secretion as measured by the CL_{cr}-to-CL_{inulin} ratio, consistent with earlier reports. Gault et al.[97] also evaluated the performance of the Cockcroft-Gault estimator of renal function compared with inulin and ^{99m}Tc-DPTA. Except for conditions of unstable kidney function, it performed like the 24-hour creatinine clearance method (Table 50–5).

Patients undergoing screening for participation in the African American Study of Kidney Disease (AASK) were evaluated for kidney function based on an estimated CL_{cr} compared with the simultaneous ^{125}I-iothalamate and measured 24-hour CL_{cr}.[98] The simultaneous CL_{cr} provided the best estimate of GFR. Cockcroft-Gault was the preferred method for estimation of GFR, based on performance and ease of use. This method was noted to underestimate the GFR by 9%, perhaps because of the increased excretion rate of creatinine by black patients.[98,99]

Administration of cimetidine has also resulted in improved performance of the Cockcroft-Gault equation to predict GFR. Ixkes et al.[100] gave patients three 800 mg doses of cimetidine in 24 hours and measured creatinine plasma levels from 3 to 7 hours following the final dose. During this 4-hour period, the $CL_{iothalamate}$ was determined as the measure of GFR. The Cockcroft-Gault calculations were performed with the plasma creatinine measurement 3 hours after the last dose of cimetidine. The ratio of the Cockcroft-Gault estimated CL_{cr}-to-$CL_{iothalamate}$ ratio decreased from 1.28 ± 0.21 to 0.98 ± 0.11 in the presence of cimetidine. This cimetidine dosing schedule also improved the accuracy of Cockcroft-Gault estimates relative to GFR in renal transplant patients with GFR values ranging from 20 to 80 mL/min/1.73 m^2 (0.19–0.77 mL/s/m^2).[101,102]

Liver Disease

The prediction of CL_{cr} or GFR is particularly problematic in patients with preexisting liver disease and renal impairment. Lower than expected serum creatinine values may result from reduced muscle mass, protein-poor diet, diminished hepatic synthesis of creatine (a precursor of creatinine), and fluid administration and can lead to significant overestimation of creatinine clearance. Orlando et al.[103] evaluated 10 healthy subjects, 10 patients with mild liver disease, and 10 with severe liver disease and observed a measured CL_{cr}-to-CL_{inulin} ratio of 1.05, 1.03, and 1.04 for each group, respectively. When the CL_{cr} of patients with severe liver disease was estimated using the Cockcroft-Gault equation, the resultant ratio (CL_{cr} Cockcroft-Gault to CL_{inulin}) was 1.23. Lam et al.[104] likewise noted an overprediction by Cockcroft-Gault of the measured CL_{cr} in patients with severe disease, by 40% to 100%.

Studies of renal function in patients with severe hepatic disease confirm the earlier observations of Hull et al.[95] and Caregaro et al.,[105] who reported that measured CL_{cr} overestimated GFR by 50% in hepatic patients with a GFR of 56 ± 19 mL/min/1.73 m^2 (0.54 ± 0.18 mL/s/m^2) because of increased tubular secretion of creatinine. The effect of cimetidine administration on measured CL_{cr} was recently evaluated in a small study by Sansoe et al.[106] In 12 patients with compensated cirrhosis, serum creatinine values increased from 0.68 ± 0.11 to 0.94 ± 0.14 mg/dL (69 ± 10 µmol/L to 83 ± 12 µmol/L) during coadministration of cimetidine (1,000 mg given as 400 mg × 1, then 200 mg every 3 hours) during a 9-hour clearance period. The CL_{cr} was reduced from 138 ± 20 to 89 ± 13 mL/min (2.30 ± 0.33 to 1.49 ± 0.22 mL/s), with no change in measured GFR.

CLINICAL CONTROVERSY

In patients with liver disease, falsely low serum creatinine values frequently occur as a result of malnourishment, muscle wasting, and enhanced tubular secretion of creatinine. Preliminary data suggest that the use of cimetidine may improve the accuracy of measured creatinine clearance compared with measured GFR in patients with cirrhosis. However, the effect of this approach on methods to estimate CL_{cr} or GFR is unknown.

DeSanto et al.[107] studied 19 patients with mild liver disease whose inulin and creatinine clearances were 90 ± 4.4 and 122 ± 7 mL/min/1.73 m^2 (0.87 ± 0.042 and 1.17 ± 0.067 mL/s/m^2), respectively. The degree of overestimation of GFR by creatinine clearance was inversely correlated with GFR (r = 0.452, P <0.04). In cirrhotic patients being evaluated for liver transplant (GFR 58 ± 5.1 mL/min/1.73 m^2 [0.56 ± 0.049 mL/s/m^2]), the MDRD4, MDRD6, and Cockcroft-Gault equations significantly overestimated GFR by 30% to 50% and were imprecise estimates of GFR before and after liver transplantation.[108,109] Thus, measurement of renal function in patients with hepatic disease should be performed using a method specific for glomerular filtration, and estimation equations for GFR or creatinine clearance should be avoided.

Other Special Populations

Davis and Chandler[110] confirmed the accuracy of the Cockcroft-Gault equation to predict CL_{cr} in trauma patients with stable kidney function, and Thakur et al.[28] demonstrated its successful use in 42 paraplegic subjects. Renal transplant recipients are frequently monitored for renal function, as numerous complications may occur during the life of the allograft. Goerdt et al.[111] assessed the bias and precision with which several nomographic methods predicted GFR (iohexol clearance) in 127 patients with stable kidney function. The Cockcroft-Gault method performed poorly, overestimating iohexol clearance. This is expected, as iohexol clearance provides a true measure of GFR, whereas the Cockcroft-Gault CL_{cr} estimate is falsely high because of the tubular secretion of creatinine. Huang et al.[112] reported the inability of several CL_{cr} equations to predict renal function in hospitalized patients with advanced human immunodeficiency virus (HIV) disease. All of the prediction methods overestimated the measured 24-hour CL_{cr}. The reasons for the poor predictability of these methods are unclear, although 24-hour collection methods result in increased variability, often because of inadequate collection of urine.

Renal function assessment during pregnancy is usually performed using a 24-hour creatinine clearance determination. Quadri et al.[113] evaluated the Cockcroft-Gault method during each trimester in 34 pregnant women and compared these estimates with the measured 24-hour CL_{cr}. Prepregnancy weights were used throughout the study for the Cockcroft-Gault method, and results correlated well with the measured clearances (r^2 = 0.76). The maximal CL_{cr} occurred during the second trimester for both methods.

Unstable Renal Function

Patients with unstable kidney function present a unique situation because serum creatinine values are changing, and steady state cannot be assumed when estimating CL_{cr}. It can take several days for serum creatinine values to reach steady state in early acute renal failure, but this time can be reduced when renal function is improving. In patients with previously normal renal function, a change in the serum creatinine concentration >50% over a period of 1 day is suggestive of unstable renal function. In patients with preexisting CKD (GFR <60 mL/min/1.73 m^2 [<0.58 mL/s/m^2]), an increase in serum creatinine by 30% or more than 1 mg/dL [88 µmol/L] over a 24- to 48-hour period indicates the presence of acute renal failure. Methods to measure GFR in this population, such as ^{125}I-iothalamate clearance, are cumbersome and costly, especially in the acute care setting. Table 50–6 lists several equations for estimating renal function under these conditions.[114–116] Although these equations are commonly used to estimate CL_{cr} in patients with acute renal failure, a rigorous evaluation of the accuracy and precision of each of these proposed methods is lacking. Also lacking is a method to estimate GFR, an equivalent to the MDRD equation for patients with CKD, for patients with acute renal failure.

TABLE 50-6 Equations for the Estimation of Creatine Clearance in Adults with Unstable Renal Function

Reference	Units	Equations: Men	Equations: Women
Jelliffe[114]	mL/min	$E^{ss} = \text{wt}[29.3 - 0.203(\text{age})]$ $E^{ss}_{corr} = E^{ss}[1.035 - 0.0337(S_{cr})]$ $E = E^{ss}_{corr} - \frac{[4\text{wt}(S_{cr2} - S_{cr1})]}{\Delta t \text{ day}}$ $CL_{cr} = \frac{E}{14.4(S_{cr})}$	$E^{ss} = \text{wt}[25.1 - 0.175(\text{age})]$ $E^{ss}_{corr} = E^{ss}[1.035 - 0.0337(S_{cr})]$ $E = E^{ss}_{corr} - \frac{[4\text{wt}(S_{cr2} - S_{cr1})]}{\Delta t \text{ day}}$ $CL_{cr} = \frac{E}{14.4(S_{cr})}$
Chiou et al.[115]	mL/min	$V_d = 0.6 \text{ L}(\text{wt}^a)$ $CL_{cr} = \frac{2[28 - 0.2(\text{age})]}{14.4(S_{cr1} + S_{cr2})} + \frac{2[V_d(S_{cr1} - S_{cr2})]}{(S_{cr1} + S_{cr2})\Delta t \text{ min}} - [CrCl^{NR} \times \text{wt}^a]$	$V_d = 0.6 \text{ L}(\text{wt}^a)$ $CL_{cr} = \frac{2\text{wt}^a[22.4 - 0.16(\text{age})]}{14.4(S_{cr1} + S_{cr2})} + \frac{2[V_d(S_{cr1} - S_{cr2})]}{(S_{cr1} + S_{cr2})\Delta t \text{ min}} - [CrCl^{NR} \times \text{wt}^a]$
Brater[116]	mL/min per 70 kg	$CL_{cr} = \frac{[293 - (\text{age}) \times [1.035 - 0.01685(S_{cr1} + S_{cr2})]}{(S_{cr1} + S_{cr2})} + \frac{49(S_{cr1} - S_{cr2})}{(S_{cr1} + S_{cr2})\Delta t \text{ day}}$	$CL_{cr} = \text{Male value} \times 0.86$

CL_{cr} = creatinine clearance, $CrCl^{NR}$ = nonrenal clearance of creatinine (0.048 mL/min per kg), E = creatinine excretion, E^{ss} = steady-state creatinine excretion, E^{ss}_{corr} = corrected steady-state creatinine excretion, Δt day, = time in days between S_{cr1} and S_{cr2}, Δt min = time in minutes between S_{cr1} and S_{cr2}, S_{cr1} = first serum creatinine value, S_{cr2} = second serum creatinine value, S_{cr} = average of S_{cr1} and S_{cr2}, V_d = volume distribution of creatinine.

The equation proposed by Jelliffe is a revised dynamic model of creatinine kinetics based on theoretical estimates of creatinine production and adjusted for age and changes in serum creatinine; however, its ability to predict changes in drug clearance (and dose adjustments) has not been evaluated.[114] In the acute setting, factors previously discussed that may alter the serum creatinine concentration must be evaluated to avoid misinterpretation. The inappropriate use of the Cockcroft-Gault equation in those with acute renal failure can significantly overestimate the value of CL_{cr} when compared with equations that are designed to account for changes in serum creatinine in patients with unstable renal function.[117] It is thus, ultimately, most important to recognize that renal function in patients with acute renal failure is generally markedly lower than one would estimate using steady-state methods, and dose adjustments should be made if necessary to avoid drug toxicity (see Chapter 51 and Tables 50–7 and 50–8).

CLINICAL CONTROVERSY

Serum creatinine values can fluctuate widely in patients with unstable renal function. Although some practitioners advocate the Cockroft-Gault equation using the highest of the two serum creatinine values, others recommend calculation of CL_{cr} using either the Brater[116] or Jelliffe equation.[114]

Kidney Function in Children

Kidney function in the neonate is difficult to assess because of difficulty in urine and blood collection, the frequent presence of a non–steady-state serum creatinine, and the apparent disparity between the development of glomerular and tubular function. Preterm infants demonstrate significantly reduced GFR prior to 34 weeks, which rapidly increases and becomes similar to term infants within the first week of life.[118] Evaluation of GFR in preterm infants on day 3 of life, using an inulin infusion, failed to identify a relationship between patient weight and GFR. Gestational age, which ranged from 23.4 to 36.9 weeks (mean 30.2 weeks), however, correlated with both GFR and the reciprocal of serum creatinine. The inulin clearance increased from 0.67 to 0.85 mL/min (0.011–0.014 mL/s) in those with gestational age younger than 28 weeks versus those of 32 to 37 weeks of age, whereas S_{cr} decreased from 1.05 to 0.73 mg/dL (93–65 µmol/L), respectively. Creatinine was measured using a specific enzymatic method to avoid interference from bilirubin or drugs.[119] Creatinine clearance has also been evaluated in infants younger than 1 week of age, and values of 17.8 mL/min/1.73 m^2 (0.171 mL/s/m^2) on day 1 increased to 36.4 mL/min/1.73 m^2 (0.351 mL/s/m^2) by day 6.[120] In light of these rapid changes in GFR, estimation of GFR is not recommended for infants younger than 1 week of age. Kidney function expressed as GFR standardized to body surface area

TABLE 50-7 Scenario A (Worsening Renal Function)

J.R. is a 50-year-old man (weight 70 kg, body surface area 1.73 m^2) admitted to the intensive care unit following an automobile accident. His renal function was normal prior to admission; however, his serum creatinine has increased from 0.6 mg/dL to 3.0 mg/dL over the past 24 hours.

Equation	Cl_{cr}	Assumptions
Jelliffe[114]	24.4 mL/min	E^{ss} = 1341.2 mg/day E^{ss}_{corr} = 1306 mg/day S_{cr} = 1.8 mg/dL S_{cr1} = 0.6 mg/dL S_{cr2} = 3.0 mg/dL Δt = 1 day Wt = 70 kg
Brater[116]	19.1 mL/min	S_{cr1} = 0.6 mg/dL S_{cr2} = 3.0 mg/dL Δt = 1 day
Cockcroft-Gault[89]	29.2 mL/min	S_{cr2} = 3.0 mg/dL Wt = 70 kg

Cl_{cr} = creatinine clearance rate, Δt = time between S_{cr1} and S_{cr2}, E^{ss} = steady-state creatinine excretion, E^{ss}_{corr} = steady-state creatinine excretion corrected, S_{cr} = average serum creatinine, S_{cr1} = first serum creatinine value, S_{cr2} = second serum creatinine value, Wt = weight.

TABLE 50-8 Scenario B (Improving Renal Function)

J.R. has been in the intensive care unit for 1 week, and his status is improving. His serum creatinine has decreased from 3.0 mg/dL to 1.0 mg/dL over the past 24 hours.

Approach	Cl_{cr}	Assumptions
Jelliffe[114]	64.5 mL/min	E^{ss} = 1341.2 mg/day E^{ss}_{corr} = 1297.7 mg/day S_{cr} = 2.0 mg/dL S_{cr1} = 3.0 mg/dL S^{cr2} = 1.0 mh/dL Δt = 1 day Wt = 70 kg
Brater[116]	78.7 mL/min	S_{cr1} = 3.0 mg/dL S_{cr2} = 1.0 mg/dL Δt = 1 day
Cockcroft-Gault[89]	87.5 mL/min	S_{cr} = 1.0 mg/dL Wt = 70 kg

Cl_{cr} = creatinine clearance rate, Δt = time between S_{cr1} and S_{cr2}, E^{ss} = steady-state creatinine excretion, E^{ss}_{corr}, steady-state creatinine excretion corrected, S_{cr} = serum creatinine, S_{cr1} = first serum creatinine value, S_{cr2} = second serum creatinine value, Wt = weight.

increases with age and stabilizes at ~1 year. In older children, GFR is best assessed using standard measurement techniques for GFR. Subcutaneous administration of ^{125}I-iothalamate has been effectively used to measure GFR in children ranging in age from 1 to 20 years.[121]

Estimation of CL_{cr} as described by Schwartz et al.[122] is dependent on the child's age and length:

$$GFR = [\text{length (cm)} \times k]/(S_{cr} \text{ in mg/dL})$$

where k is defined by age group: infant (1–52 weeks) = 0.45, child (1–13 years) = 0.55, adolescent male = 0.7, and adolescent female = 0.55.

Subsequent studies verified these relationships in children with normal renal function or mild renal impairment. However, variability increases at clearance values <50 mL/min (<0.84 mL/s). Al-Harbi and Lireman[123] reported a good correlation of the predicted CL_{cr} with measured 4-hour CL_{cr} and ^{99m}Tc-DPTA (r = 0.75) in 48 pediatric renal allograft recipients 3 to 19 years of age. However, predictive performance measures of bias and precision were not reported. Fong et al.[124] evaluated the method in critically ill children (mean age 5.6 years; range 0.1–20.8 years) and concluded that the method significantly overestimated the measured CL_{cr} (bias = 45%). Pierrat et al.[125] compared the MDRD, Schwartz, and Cockcroft-Gault equations in children 3 to 19 years of age. In children younger than 12 years, the Schwartz and MDRD equations were significantly more biased than Cockcroft-Gault, and Cockcroft-Gault provided the best prediction of GFR in children older than 12 years. Because the MDRD equation was developed in the adult population, the results of these investigations suggest that further studies will be needed to clarify the value of any of these predictive methods in children. More recently, an equation for GFR based on BTP was shown to yield similar values of GFR compared with the Schwartz equation in 387 pediatric patients (age 10.7 ± 7.1 years) who underwent a ^{99m}TC-DTPA GFR scan.[55] Dose adjustments and other therapeutic decisions based on kidney function warrant appropriate measures of renal status to avoid incorrect decisions.

Kidney Function in the Elderly

Cross-sectional studies demonstrate decreased GFR as a function of age when GFR is measured as inulin, iothalamate, or creatinine clearance.[126,127] The Baltimore Longitudinal Study on Aging,[127] an evaluation of 254 normal healthy subjects, revealed that creatinine clearance decreases at the rate of approximately 0.75 mL/min/1.73 m^2/y (0.0072 mL/s/m^2/y) beginning in the fourth decade of life. These subjects were evaluated prospectively for up to 23 years. Interestingly, approximately one-third of the subjects showed no change in renal function from their baseline value, and a small number showed an increased clearance. These changes may be a result of normal physiologic changes or of subclinical insults to the kidneys initiating the events leading to chronic progressive loss of renal function. Fliser et al.[128] studied renal functional reserve in healthy young (age 23–32 years) and elderly (age 61–82 years) volunteers using an amino acid infusion technique. Inulin clearance was used as the measure of GFR, which increased 16% in young and 17% in elderly subjects following the infusion. Renal functional reserve thus appears to be maintained in healthy elderly individuals.

Interpretation of the serum creatinine concentration alone is difficult in the elderly patient primarily because of the decreased muscle mass and resultant lower production rate of creatinine. Thus, the level of serum creatinine often remains within the normal range despite a reduction in the number of functional nephrons. As renal function declines, the kidneys excrete a larger fraction of creatinine. This perpetuates the "normal" serum creatinine. Recent recommendations, such as the adoption of standardized creatinine assays by clinical laboratories and reporting of serum creatinine values to two decimal places, will likely improve the accuracy of renal function estimation in the elderly population.[75]

The Cockcroft-Gault formula[89] can be used to estimate the CL_{cr} of elderly patients. Smythe et al.[129] estimated CL_{cr} in 23 patients older than 60 years using seven different methods and compared the results with a measured 24-hour CL_{cr} determination. Estimations were performed with the actual serum creatinine concentration and also with the serum creatinine rounded up to 1 mg/dL (88 µmol/L) if the actual value was <1 mg/dL (<88 µmol/L). Rounding the serum creatinine to 1 mg/dL (88 µmol/L) resulted in a significantly lower estimate of measured creatinine clearance (−28.8 mL/min [−0.481 mL/s]) compared with the unadjusted serum creatinine (+2.3 mL/min [+0.038 mL/s]). When capping serum creatinine values at 0.68 mg/dL (60 µmol/L), estimation of GFR using the MDRD equation overestimated creatinine clearance by up to 50 mL/min (0.84 mL/min).[130] Until further data are available, fixing or rounding serum creatinine concentration to an arbitrary value in elderly patients is not recommended.

An alternative to the estimation of GFR or a 24-hour clearance determination is a 4-hour clearance performed during water diuresis. This approach correlated with the inulin clearance as well as with an inpatient 24-hour CL_{cr}.[86] However, one must be aware of the potential risk of hyponatremia in the geriatric patient who is unable to tolerate an oral water load, as well as the need for complete bladder emptying to ensure accurate results. O'Connell et al.[131] assessed the accuracy of 2- and 8-hour urine collections compared with 24-hour creatinine clearance determinations in 45 hospitalized patients older than 65 years with indwelling urethral catheters. Single, timed urine collections for CL_{cr} showed minimal bias with the 8-hour collection compared with the 24-hour value, whereas the 2-hour determination was both biased and imprecise.

APPLICATION OF RENAL FUNCTION ESTIMATION EQUATIONS FOR DRUG DOSING

As stated previously, creatinine clearance estimated using the Cockcroft-Gault equation remains the most common approach for stratifying patients in pharmacokinetic studies in clinical development and is reported most often in FDA-approved package inserts for new drug entities.[4] A recent survey of pharmacy practitioners indicated that over 95% of individuals use the Cockcroft-Gault

equation, or a variation using ideal or lean body weight in obese patients, when applied to renal drug dosing. Use of other equations to estimate CL_{cr} may result in drug-dosing errors. For example, Wright et al.[132] showed that use of the Jelliffe equation in place of the Cockcroft-Gault to calculate the carboplatin dose resulted in obese patients having a 62% lower frequency of dose reductions and toxicity, yet a higher rate of cancer progression, when compared with nonobese patients. Thus, underestimation of GFR resulted in a lower carboplatin dose when compared with the Cockcroft-Gault method. Other modifications to the Cockcroft-Gault equation, including adjustments (or rounding) in serum creatinine to account for "low" serum creatinine values in the elderly, may also result in drug-dosing errors. In patients older than 60 years with serum creatinine < 1 mg/dL (<88 μmol/L), rounding the serum creatinine value up to 1 mg/dL (88 μmol/L) resulted in dose estimates for gentamicin that were significantly lower (−90 ± 67 mg/day) than doses calculated based on the actual serum creatinine value.[129] In a study by Roberts et al.[130] of elderly subjects (age 65 ± 13 years), rounding serum creatinine values up to a minimum of 0.68 mg/dL (60 μmol/L) resulted in CLcr estimates that were highly correlated with gentamicin clearance. Although the impact of this rounding approach on errors in drug dosing was not reported, the evidence to date indicates that rounding of serum creatinine values to an arbitrary value should be avoided because of the potential for underdosing drugs, especially in the elderly.

The automated reporting of eGFR in the clinical setting has led some practitioners to consider substituting eGFR in place of CL_{cr} for renal dose adjustments. Concerns with this approach include the uncertainty of applying eGFR values to CL_{cr}-based algorithms in package inserts and potential dosing errors and toxicity, especially for drugs with narrow therapeutic indices.[133–135] Recent studies in over 1,200 patients with renal disease have shown that overestimation of renal function using the MDRD equation results in 30% to 60% higher doses for digoxin, amantadine, and various antimicrobials compared with doses calculated using Cl_{cr} estimates.[136–139] A recent study by Stevens et al.[140] reported that use of a back-corrected value of eGFR, based on a calculated body surface area (BSA), yields dose calculations that are similar to those calculated using a measured (iothalamate) GFR. Use of this back-correction approach has not been validated, and calculating BSA in clinical settings is inconvenient and unlikely to occur. Without back-correction of the eGFR value, the significantly higher estimate of renal function may result in dosing errors; this approach is therefore not warranted until studies are conducted to assess the relationship between eGFR estimations and a drug's pharmacokinetic parameters and/or pharmacodynamic end points. A more detailed discussion of application of renal function estimates and renal dosing approaches is provided in Chapter 56.

ASSESSMENT OF PROGRESSION

Chronic kidney disease (see Chapter 52) will eventually lead to end-stage renal disease (see Chapter 53), necessitating dialysis (see Chapter 54) or transplantation for survival (see Chapter 98). The rate of progression can be slowed and in some cases halted through dietary modification, strict blood pressure control, initiation of angiotensin-converting enzyme inhibitor or angiotensin receptor blocker therapy to reduce urinary protein excretion, and improved glucose control in patients with diabetes mellitus (see Chapter 52). The efficacy of these interventions is optimally assessed with the sequential measurement of an accurate and sensitive index of GFR, such as iohexol, iothalamate, or radioisotope clearance.[141]

8 Alternatively, newer methods to estimate GFR, such as cystatin C and the MDRD4 equation, and traditional methods, such as the linear decline in the reciprocal of the serum creatinine concentration as a function of time, are simple clinical tools that can be used to evaluate the rate of progression of renal disease and to predict the time when dialysis will be needed.[2,20]

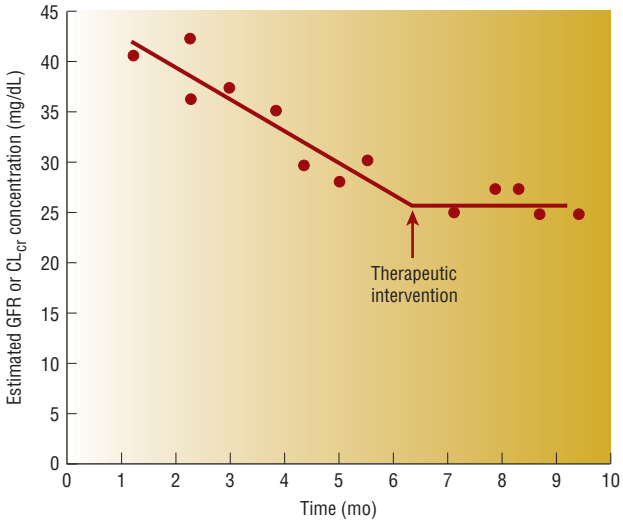

FIGURE 50-3. Illustration of the estimated glomerular filtration rate (eGFR) or creatinine clearance (CL_{cr}) decline over time and change in renal function in a hypothetical patient with progressive renal impairment. The *arrow* indicates a change in the rate of progression, which may be related to a therapeutic intervention.

Figure 50–3 depicts the change in estimated GFR or CL_{cr} over time in a typical patient with progressive CKD. Clinicians can use the eGFR or CL_{cr} plotted as a function of time as a prognostic tool, to predict when dialysis may be needed (CL_{cr} <20 mL/min [<0.33 mL/s]) or as a marker for evaluating the success of therapeutic interventions to alter the rate of decline in renal function. Several factors, such as changes in dietary intake of creatinine and decreased muscle mass, which are associated with a reduction in the production of creatinine, may alter the utility of the relationship. Microalbuminuria has been identified as an early marker of renal disease in patients with diabetic nephropathy[142] and numerous other conditions, such as hypertension and obesity.[143,144] Albuminuria is a more sensitive marker than total protein for monitoring CKD progression, as well as a modifiable risk factor for renal disease progression and cardiovascular disease.[41] Thus, patients with microalbuminuria (30–300 mg/day) on at least two or three occasions or overt albuminuria (>300 mg/day) should begin to receive pharmacotherapy. For children, microalbuminuria is considered present if albumin excretion exceeds 0.36 mg/kg/day, and overt albuminuria has been defined as an excretion rate that exceeds 4 mg/kg/day. The urinary albumin-to-creatinine ratio is also an accurate predictor of 24-hour proteinuria, a marker of renal disease. Guidelines for monitoring indicate that a urine albumin-to-creatinine ratio of >30 mg/g (>3.4 mg/mmol) places the patient at increased risk of developing diabetic nephropathy and is an indication for the initiation of pharmacotherapeutic intervention.[19] Microalbuminuria has also been suggested as a risk factor for renal dysfunction among patients with essential hypertension.[145]

MEASUREMENT OF RENAL PLASMA AND BLOOD FLOW

Measurement of renal plasma and blood flow is rarely if ever determined in the clinical setting; rather, it is reserved for research settings to evaluate hemodynamic changes related to disease or drug therapy. The kidneys receive ~20% of cardiac output, and

representative values of renal blood flow in men and women of about 1,200 ± 250 and 1,000 ± 180 mL/min/1.73 m^2 (11.6 ± 2.4 and 9.6 ± 1.7 mL/s/m^2), respectively, have been reported.[146] Renal plasma flow (RPF) is estimated to be 60% of blood flow if it is assumed that the average hematocrit is 40% and that it can be measured by the use of model compounds that are eliminated from the plasma compartment on a single pass through the kidneys. Because only 20% of the plasma is filtered at the glomerulus, the compound must undergo active tubular secretion and minimal to no reabsorption to be completely eliminated. To accurately reflect RPF, the extraction through the kidney must be nearly 100%. PAH is an organic anion that has been used extensively for the quantification of renal plasma flow. It is ~17% bound to plasma proteins and is eliminated extensively by active tubular secretion. Because PAH elimination is active, saturation of the transport processes should be anticipated, and concentrations of PAH in plasma should not exceed 10 to 20 mg/L. Dowling et al.[147] used a sequential infusion technique and observed concentration-dependent renal clearance of PAH at concentrations >100 mg/dL (1,000 g/L). Furthermore, PAH is also metabolized, possibly within the kidney, to *N*-acetyl-PAH, and it is important for the analytical method to differentiate the parent compound and metabolite.[65] Prescott et al.[148] noted that the renal clearance of PAH decreases at low plasma concentrations, whereas the clearance of the acetyl metabolite increases. Further studies are necessary to evaluate the mechanisms and significance of these findings. The extraction ratio (ER) for PAH is 70% to 90% at plasma concentrations of 10 to 20 mg/L; hence, the term *effective renal plasma flow* (ERPF) has been used when the clearance of PAH is not corrected for the extraction ratio or if it is assumed to be 1.[5] Normal values are about 650 ± 160 mL/min (10.9 ± 2.7 mL/s) for men and 600 ± 150 mL/min (10.0 ± 2.5 mL/s) for women.[146] Children will reach normalized adult values by 3 years of age, and ERPF will begin to decline as a function of age after 30 years, reaching about one-half of its peak value by 90 years of age. The method for calculation of ERPF is based on the relationship among organ clearance, ER, and flow:

$$\text{ERPF} = \text{renal PAH CL} = \text{RPF} \times \text{ER}$$

Effective renal blood flow (ERBF) can be estimated from ERPF by assuming the extraction ratio is 1 and correcting for the red blood cell volume of the blood (hematocrit [HCT]):

$$\text{ERBF} = \text{ERPF}/(1 - \text{HCT})$$

ERPF can also be measured using the radioisotope ^{131}I-orthoiodohippurate (^{131}I-OIH) or ^{99m}Tc-mercaptoacetyltriglycine (^{99m}Tc-MAG3).[149] One important advantage of this method is its ability to measure ERPF in total or for each kidney independently, as well as its ability to produce renal images. Russell and Dubovsky,[150] using a single-injection technique, compared clearance methods with and without urine collection and showed similar results with each method.

QUANTITATIVE ASSESSMENT OF TUBULAR FUNCTION

Although GFR is the best overall indicator of renal function, it may not provide an accurate measure of tubular function, either secretory capacity or cellular function, suitable for use in the research environment.[151] Tubular secretory function can be assessed by measuring PAH transport as the prototype marker of the organic anion secretory system. N^1-methylnicotinamide (NMN) and tetraethylammonium are prototype compounds secreted by the cationic transport system and may be used as markers of cationic secretory capacity. Edwards et al.[152] demonstrated delayed recovery of NMN clearance among patients with psoriasis treated with low-dose cyclosporine, as compared with the recovery of GFR and renal blood flow. Earlier studies with NMN suggested its use to assess the effects of selected renal diseases on drug handling by the kidneys.[153] Dowling et al.[147] explored the usefulness of famotidine as a marker for cationic transport but was unable to demonstrate saturation, perhaps due to the contribution from other parallel secretory pathways, such as P-glycoprotein and multidrug resistance protein 2 (MRP2).

Furthermore, Karyekar et al.[154] demonstrated that itraconazole, a P-glycoprotein inhibitor, significantly reduced the renal tubular secretion of cimetidine in healthy individuals, suggesting that cimetidine may be used as an in vivo probe of renal P-glycoprotein function. It should also be recognized that these transport systems are not necessarily mutually exclusive. Indeed, probenecid, which is secreted by the anionic pathway, inhibits the secretion of cationic compounds. Quantitative measures of tubular transport capacity are currently limited primarily to the research setting.

Other measures of tubular function are less specific and are regarded primarily as indices of damage within the nephron. Low molecular weight proteins located in the proximal tubule, such as β_2-microglobulin, can be used as urinary biomarkers to detect early tubular toxicity for drugs such as carboplatin, ifosfamide, and etoposide.[155] The rise in β_2-microglobulin is related to an early functional defect in the proximal tubular cell. This is followed by a rise in the excretion of enzymes released as a result of structural damage of the cells and, finally, by the formation and excretion of cellular casts. Other low molecular weight proteins used as markers of tubular function are retinol-binding protein (21 kDa), protein HC (also known as α_1-microglobulin, 27 kDa), KIM-1, NGAL, interleukin-18, and fatty-acid binding proteins (FABPs).[47,156,157] These proteins are normally freely filtered at the glomerulus and then completely reabsorbed by the proximal tubule. Increases in their excretion are thus suggestive of tubular dysfunction but are not diagnostic, as an increased production rate or GFR less than 30 mL/min may lead to increased excretion. In each case, the maximal reabsorptive capacity may be exceeded, leading to net excretion of the protein.

Numerous urinary enzymes such as *N*-acetylglucosaminidase, alanine aminopeptidase, alkaline phosphatase, γ-glutamyltransferase, pyruvate kinase, glutathione transferase, lysozyme, and pancreatic ribonuclease have been used as diagnostic markers for renal disease. Jung et al.[158] compared the ability of five enzymes (*N*-acetylglucosaminidase, alanine aminopeptidase, alkaline phosphatase, γ-glutamyltransferase, and lysozyme) to detect early rejection episodes in kidney transplant patients. Only *N*-acetylglucosaminidase and alanine aminopeptidase were early predictors of rejection. *N*-acetylglucosaminidase is an enzyme contained within the lysosome of the tubular cell and is released when the lysosome is damaged, whereas alanine aminopeptidase is an enzyme of the brush border. Both markers were increased approximately 2 days earlier than serum creatinine in patients with transplant rejection.

QUALITATIVE DIAGNOSTIC PROCEDURES

Radiologic Studies

9 The etiology of kidney disease can be evaluated using several qualitative diagnostic techniques, including radiography, ultrasonography, magnetic resonance imaging (MRI), and biopsy. The standard radiograph of the kidneys, ureters, and bladder provides a gross estimate of kidney size and identifies the presence of calcifications.[70] Although an easy test to perform, the value of the information is minimal, and more detailed evaluations are

often necessary. The intravenous urogram (formerly known as intravenous pyelogram) involves the administration of a contrast agent to facilitate visualization of the urinary collecting system. It is primarily used in the assessment of structural changes that may be associated with hematuria, pyuria, or flank pain, resulting from recurrent urinary tract infections, obstruction, or stone formation. For patients with low GFRs, retrograde administration of dye into the ureters may be performed to facilitate visualization of the collecting system. Contrast agents are also employed during renal angiography for the assessment of renovascular disease. As a test for the diagnosis of renovascular hypertension, the captopril (angiotensin-converting enzyme inhibitor) test is a useful adjunct. Under conditions of unilateral renal artery stenosis, the affected kidney produces large quantities of angiotensin II, which constricts the efferent arteriole to maintain GFR. The administration of an angiotensin-converting enzyme inhibitor results in reduced uptake of the contrast agent because the efferent arteriole is dilated, thereby decreasing the perfusion pressure of the affected kidney. For patients with bilateral disease, a decrease in uptake is observed in both kidneys.[159] Computed tomography (CT) is a cross-sectional anatomical imaging procedure based on x-ray data. The procedure is frequently performed with contrast to enhance imaging. Spiral, or helical, CT, a more recent technique, provides for three-dimensional reconstruction of tissues. CT is performed as a test for the evaluation of obstructive uropathy, malignancy, and infections of the kidney.

Renal Ultrasonography

Ultrasonography uses sound waves to generate a two-dimensional image. The echogenicity of the kidney is compared with that of an adjacent organ—liver on the right and spleen on the left—with an increased echogenicity indicating an abnormal finding. Ultrasonography can distinguish the renal pyramids, medulla, and cortex, as well as abnormalities in structure, such as those that occur with obstruction. Renal ultrasonography is also used as a guide for site localization during percutaneous kidney biopsy.

Magnetic Resonance Imaging

MRI is based on aligning hydrogen nuclei in the body with the use of a powerful magnet and applying radiofrequency pulses. The signals emitted by the hydrogen nuclei during realignment on repeated pulses allows for generation of the tissue image. Realignment times can also be altered with the use of contrast agents (gadolinium and gadopentetate), leading to increased signal intensity and improved imaging. MRI is useful for the assessment of obstruction, malignancy, and renovascular lesions. The relative advantages and limitations of these procedures are discussed in more detail in recent reviews.[70,160]

Biopsy

Renal biopsy is used in several conditions to facilitate diagnosis when clinical, laboratory, and imaging findings prove inconclusive. Proteinuria and hematuria are both associated with renal parenchymal disease. When less invasive studies are unsuccessful in differentiating the cause, and the possible causes have different therapeutic approaches, biopsy may be indicated. The functional status of the kidney is not assessed with biopsy, and the severity of disease and progression are best measured using the quantitative tests discussed above. Contraindications to renal biopsy include a solitary kidney, severe hypertension, bleeding disorder, severe anemia, cystic kidney, and hydronephrosis. Complications resulting from biopsy primarily include hematuria, which may last for several days, and perirenal hematoma.[19]

CONCLUSION

The prevalence of kidney disease has increased dramatically over the past 2 decades, indicating a need for early identification, risk classification, and monitoring of renal function in patients with CKD. Comprehensive approaches to evaluating renal function in the clinical setting include the Cockcroft-Gault equation for estimating creatinine clearance and drug dosing, estimation of GFR in patients with CKD, and measurement of urinary protein excretion or albumin-to-creatinine ratio as a marker of the integrity of the glomerular basement membrane. The optimal care of patients identified as having CKD involves treatment modalities aimed at slowing or halting the progression of disease, as described in Chapter 51. Accurate measurement of GFR using exogenous administration of inulin, iothalamate, or radioisotope techniques such as ^{99m}Tc-DPTA is typically reserved for research settings to assess drug therapy outcomes and the progression of disease. Use of qualitative assessments of renal function, such as radiography, CT, MRI, sonography, and biopsy, can help to determine the underlying cause of kidney disease.

ABBREVIATIONS

AUC: Area under the plasma concentration versus time curve

CKD: Chronic kidney disease

CKD-EPI: Chronic kidney disease epidemiology collaboration

CL: Clearance

CL_{cr}: Creatinine clearance

C_{ss}: Concentration of a substance in plasma under steady-state conditions

CT: Computed tomography

eGFR: Estimated glomerular filtration rate

ER: Extraction ratio

ERBF: Effective renal blood flow

ERPF: Effective renal plasma flow

GFR: Glomerular filtration rate

HCT: Hematocrit

IBW: Ideal body weight

MDRD: Modification of Diet in Renal Disease study

NKF: National Kidney Foundation

PAH: Para-aminohippuric acid

S_{cr}: Serum creatinine

U_{cr}: urine creatinine concentration

CHAPTER 51

Acute Kidney Injury

WILLIAM DAGER AND JENANA HALILOVIC

KEY CONCEPTS

1. Risk, Injury, Failure, Loss of Kidney Function, and End-Stage Renal Disease (RIFLE) and Acute Kidney Injury Network (AKIN) criteria are two classification systems used to stage the severity of AKI. Both RIFLE and AKIN classes are based on separate criteria for serum creatinine (S_{cr}) and urine output.
2. Acute kidney injury (AKI) is a common complication in the hospitalized patient and is associated with a high mortality rate.
3. AKI is predominantly categorized based on the anatomical area of injury or malfunction: (a) prerenal—decreased renal blood flow, (b) intrinsic—a structure within the kidney is damaged, and (c) postrenal—an obstruction is present within the urine collection system.
4. Conventional formulas used to calculate the glomerular filtration rate (GFR) and creatinine clearance should not be used to estimate renal function in patients with AKI. Instead, a change in S_{cr} from baseline and urine output information are more useful in determining the trend and severity of AKI. Currently, several novel biomarkers are being explored to aid in early detection and outcome prediction of AKI.
5. Prevention is key; there are very few therapeutic options for the management of established AKI.
6. Supportive management remains the primary approach to prevent or reduce the complications associated with severe AKI. Supportive therapies include renal replacement therapies (RRTs), nutritional support, avoidance of nephrotoxins, and blood pressure and fluid management.
7. For those patients with prolonged or severe AKI, RRTs are the cornerstone of support and facilitate an aggressive approach to fluid, electrolyte, and waste management.
8. Diuretic resistance is a common phenomenon in the patient with severe AKI and can be addressed with aggressive sodium restriction, combination diuretic therapy, or a continuous infusion of a loop diuretic.
9. Drug-dosing regimens for AKI patients receiving intermittent hemodialysis (IHD) are predominantly extrapolated from data derived from patients with chronic kidney disease (CKD); however, important pharmacokinetic differences exist in patients with severe AKI that should be considered.
10. Drug-dosing guidelines for AKI patients receiving continuous renal replacement therapies (CRRTs) are poorly characterized, and individualized doses may need to be determined by estimating the clearance of medications associated with a high risk of toxicity by the patient and the CRRT procedure.

The complete chapter, learning objectives, and other resources can be found at **www.pharmacotherapyonline.com**.

The development of acute kidney injury (AKI) leading to acute renal failure (ARF) presents a difficult challenge to the clinician because there are many possible causes, and the onset may be asymptomatic. A thorough patient workup is often necessary and includes past medical and surgical history, medication use, physical examination, and multiple laboratory tests. The consequences of AKI can be serious, especially in hospitalized patients, among whom complications and mortality are particularly high. Supportive therapy is the focus of management for those with established AKI, as there is no therapy that directly reverses the injury associated with its numerous causes. Management goals include maintenance of blood pressure, fluid, and electrolyte homeostasis, all of which may be dramatically altered. Additional therapies designed to eliminate or minimize the insult that precipitated AKI include discontinuation of the offending drug (i.e., the nephrotoxin), aggressive hydration, maintenance of renal perfusion, and specific maneuvers to limit or reverse the kidney injury. Because of the poor clinical outcomes and lack of specific therapies, the importance of preventing AKI cannot be overemphasized. Individuals at highest risk, such as those with preexisting organ failure, including chronic kidney disease (CKD), and the elderly with chronic medical conditions, need to be identified and their exposure to harmful diagnostic or therapeutic procedures or medications minimized.

Renal replacement therapies (RRTs), such as hemodialysis and peritoneal dialysis, have been available for decades but have not resulted in dramatic improvements in the outcomes of patients with AKI. However, newer RRT modalities, including an array of continuous renal replacement therapies (CRRTs), appear to offer some benefits, although available resources may limit their use, and drug dosing is challenging due to a paucity of data. Despite the supportive care that CRRTs offer, the development of AKI is frequently a catastrophic event. In this chapter, the epidemiology and multiple etiologies of AKI, as well as the clinical features associated with the most common types of AKI, are presented. Methods to recognize and identify the extent of functional loss are also discussed. Finally, preventive strategies and management approaches for those with established AKI are reviewed.

DEFINITION OF ACUTE KIDNEY INJURY

Before the first consensus definition of acute kidney injury was published in 2004, there was no agreement on the diagnostic criteria of this complex disorder. Acute renal failure (ARF) was the term commonly used to describe an abrupt decrease in the glomerular filtration rate (GFR) or the more clinically available index of renal function, creatinine clearance (CL_{cr}). The major challenge of using the term ARF was the lack of a universally accepted clinically relevant definition. In fact, more than 30 definitions for ARF have been reported in the medical literature, making comparisons and understanding of epidemiology, treatment, and patient outcome between studies difficult.[1] In 2004, the Acute Dialysis Quality Initiative (ADQI) group published a new consensus-derived definition and classification system for ARF called the Risk, Injury, Failure, Loss of Kidney Function, and End-Stage Kidney Disease (RIFLE) classification. The Risk, Injury, and Failure classes describe the three grades of renal dysfunction based on increasing severity. The patient is assigned a class based on the more severe change in the separate criteria of serum creatinine (S_{cr}) or urine output. Because the S_{cr} criteria are based on its change from baseline, the patient's renal function prior to the development of renal failure needs to be known. If the baseline measure of S_{cr}, CL_{cr}, or GFR is not available, and the patient has no history of renal dysfunction, one can estimate the baseline S_{cr} value by using the Modification of Diet in Renal Disease (MDRD) equation with an assumed normal GFR of 75 mL/min/1.73 m^2. The last two components of the RIFLE classification are Loss of Kidney Function, defined as the need for RRT for more than 4 weeks, and End-Stage Kidney Disease (ESKD), defined as the need for RRT for more than 3 months.[2]

In 2007, the Acute Kidney Injury Network (AKIN) slightly modified the RIFLE criteria (see Table 51–1 for an overview of both classification systems). The term acute renal failure was replaced by acute kidney injury to emphasize that the disorder exists along a wide continuum, ranging from mild renal dysfunction to the need for RRT. RIFLE-Risk, RIFLE-Injury, and RIFLE-Failure were replaced by AKIN stages 1, 2, and 3, respectively; Loss and End-Stage Kidney Disease were removed from the staging system but retained as outcomes. Also, a time frame of 48 hours was added as a diagnostic criterion to ensure that the process was indeed acute in nature. In an effort to increase the sensitivity of the RIFLE criteria, the change in S_{cr} was lowered from 0.5 mg/dL (44 µmol/L) to 0.3 mg/dL (27 µmol/L) for RIFLE-Risk class. Finally, AKIN criteria place all patients receiving RRT automatically into AKIN stage 3.[3]

1 So far, the RIFLE classification has gained more recognition than the AKIN staging system, mostly because of the greater number of validation studies published. In addition, the few studies that have compared the RIFLE scoring system with the newly proposed AKIN criteria in critically ill patients have noted no difference in sensitivity or ability to predict outcome.[4,5]

Since the consensus guidelines on AKI were published, multiple studies have validated the ability of the RIFLE criteria to predict certain patient outcomes, particularly hospital mortality.[6,7] When compared with patients without AKI, mortality increases proportionally with the severity of renal dysfunction.[8] This increased risk of death may even persist in patients who recover their renal function after an AKI episode.[9] In addition, AKI is associated with increased length of hospital stay, ventilator days, need for RRT, and development of CKD and ESKD.[10]

Even though the RIFLE and AKIN staging systems have led to a standardized and widely accepted classification of AKI, their dependence on S_{cr} and urine output as the main diagnostic criteria is associated with some inherent weaknesses. An increase in S_{cr} is usually evident about 1 or 2 days after development of AKI. This lag time in S_{cr} rise may significantly delay diagnosis of AKI and adversely affect patient outcomes. Urine output reduction emerges earlier in AKI but is a very nonspecific marker because it may not always be present. In fact, patients with AKI can either be anuric (urine output <50 mL/day), oliguric (urine output <500 mL/day), or nonoliguric (urine output >500 mL/day). Urine output will also vary with volume status, diuretic administration, and presence of obstruction.[11]

EPIDEMIOLOGY

The epidemiology of AKI has been poorly characterized in part due to the lack of a standardized definition, differences in the population under study, and geographical location. AKI is considered to be an uncommon condition in the community-dwelling, generally healthy population, with an annual incidence depending on the definition that ranges from 0.01% to 0.06% (Table 51–2).[12] On the other hand, AKI is significantly more common in hospitalized individuals, with a reported incidence of 7% to 18%. Intensive care unit (ICU) patients have the highest risk of developing AKI, with 36% to 67% of critically ill patients being affected.[6,7]

2 Increased mortality and morbidity are two well-recognized complications of AKI. Any degree of renal dysfunction is associated with an increased risk of death, particularly if the patient does not recover his or her baseline renal function at the time of hospital discharge.[13] The odds of death increase further with the severity of the RIFLE category.[14] For survivors of AKI, the development of

TABLE 51-1 RIFLE and AKIN Classification Schemes for Acute Kidney Injury[a]

RIFLE category	S_{cr} or GFR criteria	Urine output criteria
Risk	S_{cr} increase to 1.5-fold or GFR decrease >25% from baseline	<0.5 mL/kg/h for ≥6 h
Injury	S_{cr} increase to 2-fold or GFR decrease >50% from baseline	<0.5 mL/kg/h for ≥12 h
Failure	S_{cr} increase to 3-fold or GFR decrease >75% from baseline, or S_{cr} ≥4 mg/dL (≥354 µmol/L) with an acute increase of at least 0.5 mg/dL (44 µmol/L)	Anuria for ≥12 h
Loss	Persistent acute renal failure = complete loss of function (RRT) for >4 weeks	
ESKD	RRT >3 months	
AKIN criteria	**S_{cr} criteria**	**Urine output criteria**
Stage 1	S_{cr} increase ≥0.3 mg/dL (≥27 µmol/L) or 1.5- to 2-fold from baseline	<0.5 mL/kg/h for ≥6 h
Stage 2	S_{cr} increase >2- to 3-fold from baseline	<0.5 mL/kg/h for ≥12 h
Stage 3	S_{cr} increase >3-fold from baseline or S_{cr} ≥4 mg/dL (≥354 µmol/L), with an acute increase of at least 0.5 mg/dL (44 µmol/L) or need for RRT	<0.3 mL/kg/h for ≥24 h or anuria for ≥12 h

[a]AKIN criteria require a time constraint of 48 hours for diagnosis. GFR decreases are specified only by RIFLE. In both cases, the criterion that leads to the worst possible diagnosis should be used.
AKIN = Acute Kidney Injury Network, ESKD = end-stage kidney disease, GFR = glomerular filtration rate, RIFLE = Risk, Injury, Failure, Loss of Kidney Function, and End-Stage Renal Disease, RRT = renal replacement therapy, S_{cr}, serum creatinine.

TABLE 51-2 Incidence and Outcomes of Acute Kidney Injury

	Community-Acquired AKI	Hospital-Acquired AKI	ICU-Acquired AKI
Incidence	Low (<1%)	Moderate (7–20%)	High (35–70%)
Cause	Single	Single or multiple	Multifactorial
Overall mortality rate (%)	~15%	15–40%	30–90%
Common risk factors	Poor fluid intake, dehydration, drugs (ACEIs, ARBs, diuretics, NSAIDs, chemotherapy), infection, trauma, rhabdomyolysis	Volume depletion, hypotension, low cardiac output, nephrotoxic drugs, radiocontrast dyes	Sepsis/septic shock, major surgery, multiorgan failure, hypotension, low cardiac output, nephrotoxic drugs

ACEIs, angiotensin-converting enzyme inhibitors; AKI, ACE = angiotensin-converting enzyme, AKI = acute kidney injury, ARBs = angiotensin receptor blockers, ICU = intensive care unit; NSAIDs = nonsteroidal antiinflammatory drugs.

some degree of CKD and need for RRT are other important considerations.[15] Long-term follow-up studies indicate that patients continue to recover renal function up to 6 months after hospital discharge. Even though the majority of patients will recover normal kidney function, ~25% will have CKD, and 12.5% will remain dialysis-dependent.[16]

ETIOLOGY

3 The etiology of AKI can be divided into broad categories based on the anatomic location of the injury associated with the precipitating factor(s). The management of patients presenting with this disorder is largely predicated on identification of the specific etiology responsible for the patient's current AKI (Fig. 51–1). Traditionally, the causes of AKI have been categorized as (a) prerenal, which results from decreased renal perfusion in the setting of undamaged parenchymal tissue, (b) intrinsic, the result of structural damage to the kidney, most commonly the tubule from a ischemic or toxic insult, and (c) postrenal, caused by obstruction of urine flow downstream from the kidney (Fig. 51–2).

Community-acquired AKI most commonly occurs secondary to renal hypoperfusion from volume depletion (dehydration, vomiting, and diarrhea), heart failure, or the ingestion of medications such as angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs). Other less common causes include infection (e.g., human immunodeficiency virus [HIV] nephropathy), trauma, rhabdomyolysis, and vascular events.[12,17] The most common cause of hospital- and intensive care unit (ICU)–acquired AKI is intrinsic, occurring as the result of ischemic or toxic acute tubular necrosis (ATN). The presence of underlying CKD increases the risk of AKI threefold. Other risk factors for developing AKI are advanced age (>65 years), multisystem organ failure, sepsis, preexisting chronic diseases, drugs, infection, surgery, malignancy, and bone marrow or solid organ transplantation.[12,18] It has been suggested that certain genetic polymorphisms responsible for vascular and inflammatory processes may contribute to the large variability in patient susceptibility to AKI.[19] However, evidence has been relatively inconclusive, and more research with higher quality studies will be necessary to confirm current findings.

PATHOPHYSIOLOGY

PSEUDORENAL KIDNEY INJURY

Pseudorenal AKI is characterized by a rise in either the blood urea nitrogen (BUN) or the S_{cr}, which misleadingly may suggest the presence of renal dysfunction, when in fact GFR is not diminished. This could be the result of cross-reactivity with the assay used to measure the BUN or S_{cr} or selective inhibition of the secretion of creatinine into the proximal tubular lumen by certain medications (see Chapter 50). The initiation or discontinuation of such agents should be considered in the assessment for acute changes in renal function and should be looked for as part of the workup in any patient who is suspected of having AKI.

PRERENAL ACUTE KIDNEY INJURY

Prerenal AKI or prerenal azotemia results from hypoperfusion of the renal parenchyma, with or without systemic arterial hypotension. Renal hypoperfusion with systemic arterial hypotension may be caused by a decline in either the intravascular volume or the effective circulating blood volume. Intravascular volume depletion may result from several conditions, including hemorrhage, excessive gastrointestinal (GI) losses (severe vomiting or diarrhea), dehydration, extensive burns, and diuretic therapy. Effective circulating blood volume may be reduced in conditions associated with a decreased cardiac output and systemic vasodilation (e.g., sepsis). Renal hypoperfusion without systemic hypotension is most commonly associated with bilateral renal artery occlusion or unilateral occlusion in a patient with a single functioning kidney.

Patients with a mild reduction in effective circulating blood volume or volume depletion are generally able to maintain a normal GFR by activating several compensatory mechanisms. Those initial physiologic responses by the body stimulate the sympathetic nervous and the renin–angiotensin–aldosterone system and release antidiuretic hormone if hypotension is present. These responses work together to directly maintain blood pressure via vasoconstriction and stimulation of thirst, which in conscious patients results in increased fluid intake, as well as sodium and water retention. Additionally, GFR may be maintained by afferent arteriole dilation (mediated by intrarenal production of vasodilatory prostaglandins, kallikrein, kinins, and nitric oxide) and efferent arteriole constriction (mainly mediated by angiotensin II). In concert, these homeostatic mechanisms are often able to maintain arterial pressure and renal perfusion, potentially averting the progression to AKI.[20] If, however, the decreased renal perfusion is severe or prolonged, these compensatory mechanisms may be overwhelmed, and prerenal AKI will then be clinically evident.

Patients at risk for prerenal AKI are particularly susceptible to changes in the afferent and efferent arteriolar tone, as they may not be able to compensate as readily. Certain drug classes can interfere with these renal adaptive responses that are normally responsible for maintaining adequate renal perfusion. The resulting reduction in the glomerular hydrostatic pressure precipitates an abrupt decline in GFR and is sometimes referred to as functional AKI. A common cause of this syndrome is a decrease in efferent arteriolar resistance as the result of initiation of an ACE inhibitor or ARB (see Chapter 55) For example, individuals with heart failure are often given an ACE inhibitor or ARB to help improve left ventricular function, but if the dose is titrated too rapidly, they may experience

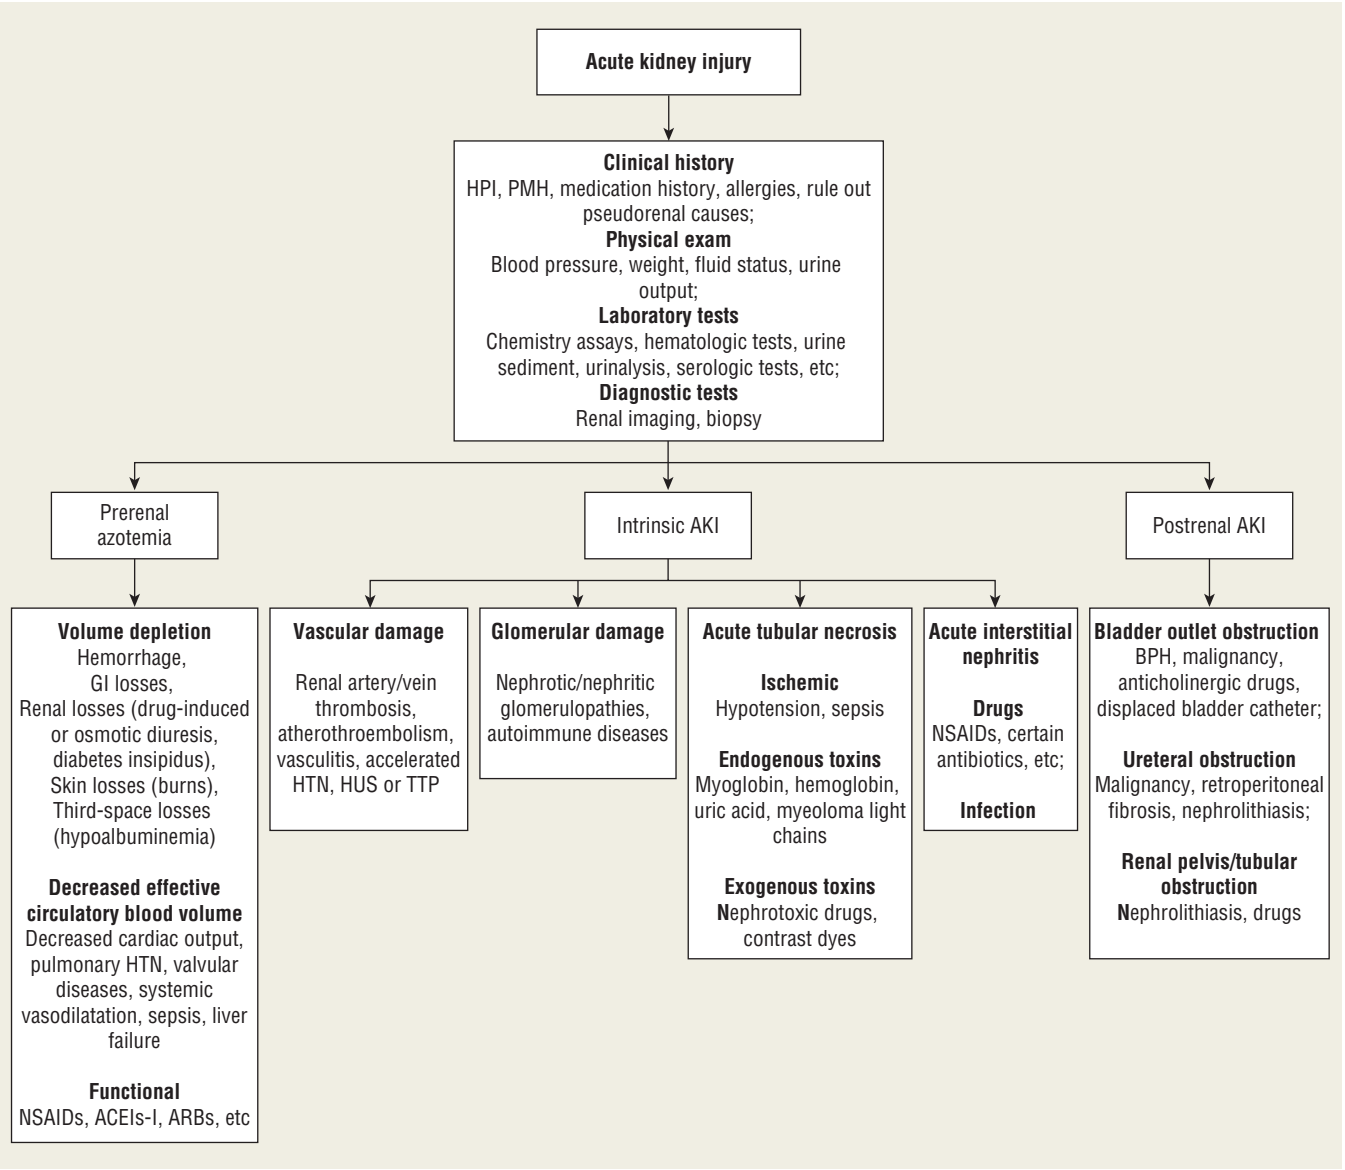

FIGURE 51-1. Classification of acute kidney injury (AKI) based on etiology. (ACEIs, angiotensin-converting enzyme inhibitors; ARBs, angiotensin receptor blockers; BPH, benign prostatic hyperplasia; GI, gastrointestinal; HTN, hypertension; HUS, hemolytic uremic syndrome; NSAIDs, nonsteroidal antiinflammatory drugs; TTP, thrombotic thrombocytopenic purpura.

a decline in their GFR. If the increase in the S_{cr} is less than 30% from baseline, the medication can be continued. Another classic example is initiation of ACE inhibitors or ARBs in patients with renovascular disease. It is estimated that ACE inhibitor–induced renal failure occurs in 6% to 23% of patients with bilateral renal artery stenosis and in ~38% of patients with unilateralstenosis who have a single kidney.[21] As a result, administration of ACE inhibitor or ARB therapy in the presence of those conditions is contraindicated. Nonsteroidal antiinflammatory drugs (NSAIDs) may also initiate AKI in susceptible individuals. NSAIDs inhibit renal prostaglandin production and afferent arteriolar vasodilation, which some patients rely on to maintain renal perfusion and GFR. Patients at risk for NSAID-induced AKI include those with CKD, volume depletion, and decreased effective circulating blood volume.[22]

If the causes of renal hypoperfusion are promptly corrected, prerenal AKI can be reversed and renal function returned to the patient's normal baseline in a matter of days. Prolonged prerenal azotemia, in contrast, can cause direct (and potentially irreversible) injury to the renal parenchyma and lead to development of ischemic ATN[23] (see the review of intrinsic AKI below).

INTRINSIC ACUTE KIDNEY INJURY

Intrinsic AKI results from direct damage to the kidney and is categorized on the basis of the injured structures within the kidney: the renal vasculature, glomeruli, tubules, and interstitium. Many diverse mechanisms associated with the development of intrinsic AKI are categorized in Figure 51–1.

Renal Vasculature Damage

Occlusion of the larger renal vessels resulting in AKI is not common but can occur if large atheroemboli or thromboemboli occlude the bilateral renal arteries or one vessel of the patient with a single kidney. Atheroemboli most commonly develop during vascular procedures that cause atheroma dislodgement, such as angioplasty and aortic manipulations. Thromboemboli may arise from dislodgement of a mural thrombus in the left ventricle of a patient with severe heart failure or from the atria of a patient with atrial fibrillation. Renal artery thrombosis may occur in a similar fashion to coronary thrombosis, in which a thrombus forms in conjunction with an atherosclerotic plaque.

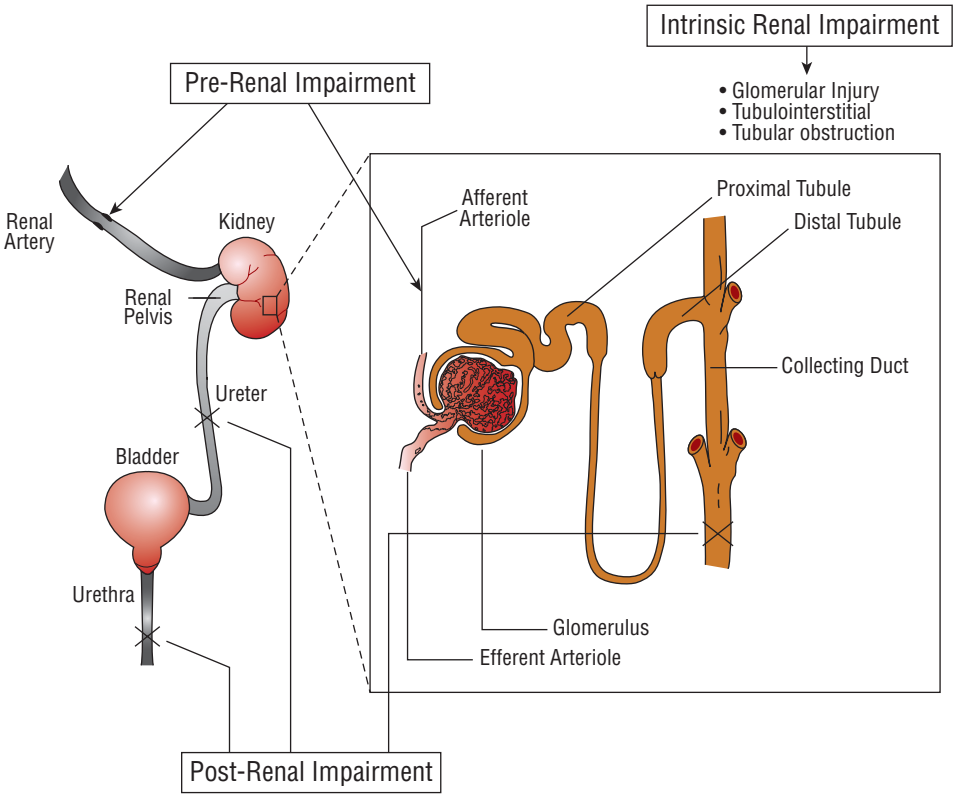

FIGURE 51-2. Physiologic classification of AKI. Blood flows through the afferent arteriole, to the glomerulus, and exits through the efferent arteriole. The formation of glomerular ultrafiltrate is dependent on the surface area of the capillaries within the glomerular region, their permeability, and the net hydrostatic pressure across the capillary wall. A decrease in blood flow and renal perfusion can lead to a prerenal reduction in renal function. Under conditions in which renal blood flow is diminished, the kidney maintains glomerular ultrafiltration by vasodilating the afferent and vasoconstricting the efferent arterioles. Medications that may interfere with these processes may result in an abrupt decline in glomerular filtration. Damage to the glomerular or tubular regions leads to intrinsic AKI. Obstruction of urine flow once in the collecting tubule, ureter, bladder, or urethra is termed postrenal impairment.

Although smaller vessels can also be obstructed by atheroemboli or thromboemboli, the damage is limited to the vessels involved, and the development of significant AKI is unlikely. However, these small vessels are susceptible to inflammatory processes that lead to microvascular damage and vessel dysfunction when the renal capillaries are affected. Neutrophils invade the vessel wall, causing damage that can include thrombus formation, tissue infarction, and collagen deposition within the vessel structure. Diffuse renal vasculitis can be mild or severe, with severe forms promoting concomitant ischemic ATN. The S_{cr} is usually elevated when the lesions are diffuse; thus, the area of damage is large. Accelerated hypertension that is not treated may also compromise renal microvascular blood flow, causing diffuse renal capillary damage.

Glomerular Damage

Only 5% of the cases of intrinsic AKI are of glomerular origin. The glomerulus is one of two capillary beds in the kidney. It serves to filter fluid and solute into the tubules while retaining proteins and other large blood components in the intravascular space. Because the glomerulus is a capillary system, similar damage observed in the renal vasculature by the same mechanisms can occur in addition to severe inflammatory processes specific to the glomerulus. The pathophysiology and specific therapeutic approaches to glomerulonephritis are described in detail in Chapter 56.

Tubular Damage

Approximately 85% of all cases of intrinsic AKI are caused by ATN, of which 50% are a result of renal ischemia, often arising from an extended prerenal state. The remaining 35% are the result of exposure to direct tubule toxins, which can be endogenous (myoglobin, hemoglobin, or uric acid) or exogenous (contrast agents, aminoglycoside antibiotics, etc.). The tubules located within the medulla of the kidney are particularly at risk from ischemic injury, as this portion of the kidney is metabolically active and thus has high oxygen requirements, yet even in the best of situations, receives relatively low oxygen delivery (as compared with the cortex). Thus, ischemic conditions caused by severe hypotension or exposure to vasoconstrictive drugs preferentially affect the tubules more than any other portion of the kidney.

The clinical evolution of ATN is characterized by three distinct phases: initiation, maintenance, and recovery. The hallmarks of the initiation phase are ischemic injury and GFR reduction, both of which occur as a result of the interplay of several different pathophysiologic processes. Ischemic injury causes tubular epithelial cell necrosis or apoptosis and is followed by an extension phase with continued hypoxia and an inflammatory response involving the nearby interstitium. The loss of epithelial cells between the filtrate and the interstitium leaves the basement membrane denuded and unable to appropriately regulate fluid and electrolyte transfer across the tubular lumen. As a result, the glomerular filtrate starts leaking back into the interstitium and is reabsorbed into the systemic circulation. Additionally, urine flow is obstructed by accumulation of sloughed epithelial cells, cellular debris, and formation of casts. The onset of ATN can occur over hours to days, depending on the factors responsible for the damage to the tubular epithelial cells. Regardless of the etiology; tubular injury, back leakage, and obstruction lead to a loss in the ability to concentrate urine, decreased urine output, and, ultimately, reduction in the GFR. Continued kidney hypoxia or toxin exposure after the original insult kills more cells and propagates the inflammatory response; it also can extend the injury and delay the recovery process. With prolonged ischemia, the tubular epithelial cells in the corticomedullary junction are damaged and die.[23] When the toxin or ischemia is removed, a maintenance phase ensues and may last anywhere from a few weeks to several months. The maintenance phase is eventually followed by a recovery phase, during which new tubule cells are regenerated. The recovery phase is associated with a notable diuresis, which requires prompt attention to maintain fluid balance, or a secondary prerenal injury may occur. However, if the ischemia or injury is extremely severe or prolonged, cortical necrosis may occur, limiting tubule cell regrowth in the affected areas.[21]

Interstitial Damage

If the renal interstitium becomes severely inflamed and edematous, it can lead to development of acute interstitial nephritis (AIN). AIN may be caused by drugs (see Chapter 55), infections, and, rarely, autoimmune idiopathic diseases. Whatever the inciting event, acute interstitial injury is characterized by lesions comprised of monocytes, eosinophils, macrophages, B cells, or T cells, clearly identifying an immunologic response as the injurious process affecting the interstitium. If AIN is caused by a drug hypersensitivity reaction, most patients will regain normal renal function within several weeks if the offending drug is promptly discontinued. If symptoms of AIN remain unrecognized, and the exposure to the causative agent continues, persistent renal dysfunction associated with interstitial fibrosis and tubular atrophy may develop.[24]

POSTRENAL ACUTE KIDNEY INJURY

Postrenal AKI accounts for less than 5% of all cases of AKI and may develop as the result of obstruction at any level within the urinary collection system from the renal tubule to the urethra (see Fig. 51–1).[23] However, if the obstructing process is above the bladder, it must involve both kidneys (one kidney in a patient with a single functioning kidney) to cause significant AKI, as one functioning kidney can generally maintain a near normal GFR. Bladder outlet obstruction, the most common cause of obstructive uropathy, is often the result of a prostatic process (hypertrophy, cancer, or infection), producing a physical impingement on the urethra and thereby preventing the passage of urine. It may also be the result of an improperly placed urinary catheter. Neurogenic bladder or anticholinergic medications may prevent bladder emptying and cause AKI. The blockage may occur at the ureter level, secondary to nephrolithiasis, blood clots, sloughed renal papillae, or physical compression by an abdominal process, such as retroperitoneal fibrosis, cancer, or an abscess. Crystal deposition within the tubules from oxalate and some medications severe enough to cause AKI is uncommon, but it is possible in patients with severe volume contraction and in those receiving large doses of a drug with relatively low urine solubility (see Chapter 55). In these cases, patients have insufficient urine volume to prevent crystal precipitation in the urine.[25] Extremely elevated uric acid concentrations from chemotherapy-induced tumor lysis syndrome can cause obstruction and direct tubular injury as well. Wherever the location of the obstruction, urine will accumulate in the renal structures above the obstruction and cause increased pressure upstream. The ureters, renal pelvis, and calyces all expand, and the net result is a decline in GFR. If renal vasoconstriction ensues, a further decrement in GFR will be observed.

CLINICAL PRESENTATION

The initiating sign or symptom prompting the clinical suspicion of AKI is highly variable and largely dependent on the underlying etiology. It may be a change in urinary habits (e.g., decreased urine output or urine discoloration), sudden weight gain, or severe abdominal or flank pain. Early recognition and cause identification are critical, as they directly affect the outcome of AKI. One of the first steps in the diagnostic process is to determine if the renal complication is acute, chronic, or the result of an acute change in a patient with known CKD (also called acute-on-chronic renal failure). Patients should also be promptly evaluated for any changes in their fluid and electrolyte status. Patients presenting with AKI in the outpatient environment may have very nonspecific or seemingly unrelated symptoms so that the time of onset of the injury can be difficult to determine. On the other hand, AKI in hospitalized patients is often detected much earlier in its course due to frequent laboratory studies and daily patient assessment.

PATIENT ASSESSMENT

The assessment of a patient with AKI starts with a thorough review of his or her medical records, with a particular focus on chronic conditions, medication history, laboratory studies, procedures, and surgeries. An exhaustive review of prescription and nonprescription medicines, herbal products, and recreational drugs may help determine if AKI was potentially precipitated by drug ingestion. Overall, patient presentation varies widely, depending on the underlying cause of AKI. Table 51–3 summarizes the most common physical exam findings associated with different types of AKI.

TABLE 51-3 Physical Examination Findings in Acute Kidney Injury

Physical Examination Finding	Possible Diagnosis	Category of Acute Kidney Injury
Vital signs		
Orthostatic hypotension	Volume depletion	Prerenal
Febrile	Sepsis	Intrinsic: tubule necrosis
Skin		
Tenting	Volume depletion	Prerenal
Rash	Hypersensitivity reaction	Intrinsic: interstitial nephritis
Petechiae	Thrombotic: thrombocytopenic purpura	Intrinsic: vasculitis
	Hemolytic uremic syndrome	
	Sepsis	Intrinsic: tubule necrosis
Splinter hemorrhages Janeway lesions Osler nodes	Endocarditis	Intrinsic: glomerulonephritis
Edema	Total-body volume overload	Intrinsic or prerenal because of heart failure Other types of prerenal unlikely
HEENT		
Hollenhorst plaque	Cholesterol emboli	Intrinsic: vascular
Roth spots	Endocarditis Heart failure	Intrinsic: glomerulonephritis
Elevated jugular venous pressure	Pulmonary hypertension	Prerenal
Heart		
S_3 heart sound	Heart failure	Prerenal
New or increased murmur	Endocarditis	Intrinsic: glomerulonephritis
Lung		
Rales	Heart failure	Prerenal
Abdomen		
Renal artery bruit	Renal artery stenosis	Prerenal
Ascites	Liver failure or right-heart failure	Prerenal Hepatorenal syndrome
Bladder distension	Bladder outlet obstruction	Postrenal
Genitourinary		
Prostatic enlargement	Prostatic hypertrophy or cancer	Postrenal
Gynecologic		
Abnormal bimanual examination	Possible bilateral ureteral obstruction or cervical cancer	Postrenal

HEENT = head, eyes, ears, nose, and throat.

During the initial patient evaluation, presumptive signs and symptoms of AKI need to be differentiated from a potential new diagnosis of CKD. A past medical history for renal disease–related chronic conditions (e.g., poorly controlled hypertension and diabetes mellitus), previous laboratory data documenting the presence of proteinuria or an elevated S_{cr}, and the finding of bilateral small kidneys on renal ultrasonography suggest the presence of CKD rather than AKI. However, it is important to note that patients with CKD may develop episodes of AKI as well. In that case, an abrupt rise in the patient's baseline S_{cr} is one of the most useful indicators of the presence of an acute insult to the kidneys.

An acute change in urinary habits is another common and noticeable symptom associated with AKI. The presence of cola-colored urine is indicative of blood in the urine, a finding commonly associated with acute glomerulonephritis. In hospitalized patients, changes in urine output may be helpful in characterizing the cause of the patient's AKI. Acute anuria is typically caused by either complete urinary obstruction or a catastrophic event (e.g., shock or acute cortical necrosis). Oliguria, which often develops over several days, suggests prerenal azotemia, whereas nonoliguric renal failure usually results from acute intrinsic renal failure or incomplete urinary obstruction.

Depending on the underlying cause of AKI, patients may present with a variety of symptoms affecting virtually any organ system of the body. Constitutional symptoms such as nausea, vomiting, fatigue, and malaise are common but nonspecific. The onset of flank pain is suggestive of a urinary stone; however, if bilateral, it may suggest swelling of the kidneys secondary to acute glomerulonephritis or acute interstitial nephritis. Complaints of severe headaches may suggest the presence of severe hypertension and vascular damage. The presence of fever, rash, and arthralgias may be indicative of drug-induced acute interstitial nephritis or lupus nephritis. A recent increase in the patient's weight or complaints of tight-fitting rings secondary to salt and water retention indicate prerenal causes and may be helpful in defining the time of onset of kidney injury.

A thorough physical examination is an important step in evaluating individuals with AKI, as clues regarding the etiology can be evident from the patient's head (eye exam) to toe (evidence of dependent edema) assessment. Observations will either support or refute the cause as prerenal, intrinsic, or postrenal. Evaluation of the volume and hemodynamic status is critical as well, as it will guide patient management. For example, patients with prerenal AKI can present with either volume depletion or fluid overload. Volume depletion may be evidenced by the presence of postural hypotension, decreased jugular venous pressure (JVP), and dry mucous membranes. Fluid overload, on the other hand, is often reflected by elevated JVP, pitting edema, ascites, and pulmonary crackles.

TABLE 51-4 Diagnostic Parameters for Differentiating Causes of Acute Kidney Injury[a]

Laboratory Test	Prerenal Azotemia	Acute Intrinsic Kidney Injury[b]	Postrenal Obstruction
Urine sediment	Hyaline casts, may be normal	Graunular casts, cellular debris	Cellular debris
Urinary RBC	None	2–4+	Variable
Urinary WBC	None	2–4+	1+
Urine Na (mEq/L or mmol/L)	<20	>40	>40
FE_{Na} (% [fraction])	<1 [<0.01]	>2 [>0.02]	Variable
Urine/serum osmolality	>1.5	<1.3	<1.5
$Urine_{cr}/S_{cr}$	>40:1	<20:1	<20:1
BUN/S_{cr} (SI units)	>20 (<1:12.4)	~15 (~1:16)	~15 (~1:16)
Urine-specific gravity	>1.018	<1.012	Variable

[a]Common laboratory tests are used to classify the cause of acute kidney injury (AKI). Functional AKI, which is not included in this table, would have laboratory values similar to those seen in prerenal azotemia. However, the urine osmolality-to-plasma osmolality ratios may not exceed 1.5, depending on the circulating levels of antidiuretic hormone.

[b]The laboratory results listed under Acute Intrinsic Kidney Injury are those seen in acute tubular necrosis, the most common cause of such injury.

BUN = blood urea nitrogen, FE_{Na} = fractional excretion of sodium, RBC = red blood cell, S_{cr} = serum creatinine, WBC = white blood cell.

LABORATORY TESTS AND INTERPRETATION

CONVENTIONAL MARKERS OF KIDNEY FUNCTION

4 The commonly available laboratory tests used to evaluate the patient with renal insufficiency are described in Chapter 50, and those of particular value in the assessment of renal function in patients with AKI are highlighted in Table 51–4. Over the past 3 decades, S_{cr} has been the most widely used laboratory test for estimating creatinine clearance (by the Cockroft-Gault equation), which, in turn, was used as a surrogate marker for GFR. Only in the last 10 years has the multiple versions of the Modification of Diet in Renal Disease (MDRD) equation been used as an alternative method for determining GFR in patients with CKD.[26] Numerous other equations and markers have been proposed to estimate GFR accurately.[27] However, the Cockroft-Gault and MDRD 4-variable equations have so far remained the most widely used for estimating renal function in clinical practice.

There are several limitations associated with its use. S_{cr} varies widely with a patient's age, gender, muscle mass, diet, and hydration status. For example, patients with reduced creatinine production, such as those with low muscle mass, may have very low S_{cr} values (<0.6 mg/dL [<53 µmol/L]); thus, the presence of a gradual S_{cr} rise to normal values (0.8–1.2 mg/dL [71–106 µmol/L]) may actually indicate reduced GFR. When coupled with a decline in urine output, this might suggest the presence of AKI. However, in the presence of improved nutrition and a large muscle mass, an S_{cr} of 1.2 mg/dL (106 µmol/L) may be a true representation of a person's current renal status. Instead of using fixed numbers to determine renal function, changes in the value from a patient's baseline need to be reviewed. S_{cr} is normally inversely proportional to GFR. However, rapid changes in GFR (as they occur in AKI) disrupt this equilibrium and make S_{cr} a very insensitive marker. In fact, changes in S_{cr} will lag behind the GFR's decline due to slow accumulation, increased tubular secretion, and increased extrarenal clearance.[28] This can lead to a significant overestimation of the patient's GFR in the early stages of AKI and consequently a potential delay in the diagnosis of the disorder.

An example of this phenomenon is illustrated by an acute renal artery thrombus that results in abrupt cessation of GFR in one kidney as a consequence of the complete obstruction of blood flow to that kidney (Fig. 51–3). Although 5 minutes following the event GFR is decreased 50% (assuming the other kidney is functioning and unaffected), the S_{cr} remains unchanged. Assuming a standard daily creatinine production of ~20 mg/kg of lean body weight, one can expect ~1.4 g of creatinine production in a 24-hour period in a 70 kg individual. In pharmacokinetic terms, daily creatinine production is analogous to a continuous infusion, and GFR determines the elimination rate of creatinine. In a patient with normal renal function (GFR of 120 mL/min [2.00 mL/s]), the half-life of creatinine is 3.5 hours, with 95% of steady state achieved in ~14 hours. If GFR declines to 50%, 25%, or 10% of normal, the half-life of creatinine increases, resulting in prolongation of the time to reach 95% of steady state, specifically taking 1, 2, and 4 days, respectively.[29]

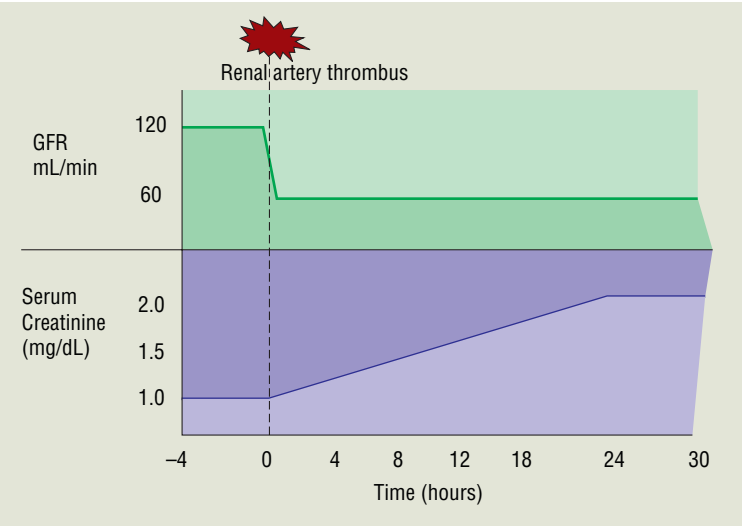

FIGURE 51-3. Glomerular filtration rate (GFR; mL/min) and serum creatinine (S_{cr}; g/dL) versus time following acute renal injury. Prior to time 0, a GFR of 120 mL/min and an S_{cr} of 1 g/dL exist. At time 0, an abrupt renal artery thrombus forms, depriving one kidney of renal blood flow. Composite GFR immediately declines by 50% to ~60 mL/min. However, S_{cr} does not increase immediately, as it is dependent on creatinine production and attainment of steady-state serum concentrations. For comparison of values to SI units, multiply serum creatinine in mg/dL by 88.4 to give units of μmol/L; multiply GFR in mL/min by 0.0167 to give units of mL/s.

Because of the challenges associated with the accuracy of S_{cr} in AKI, several GFR calculation methods, such as the Cockcroft-Gault, MDRD, and Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equations, should not be used in AKI patients with unstable renal function. These equations will typically overestimate GFR when the AKI is worsening and underestimate it when the AKI is resolving. Instead, it may be useful to evaluate changes in S_{cr} values from the patient's baseline and also consider the S_{cr} sequence values to determine if renal function is potentially improving (values declining) or worsening (values rising). The most recent S_{cr} value reflects the time-averaged kidney function over the preceding time period. Several mathematical approaches to estimate GFR in patients with unstable S_{cr} that incorporate the principles of creatinine accumulation and elimination have been proposed and are discussed in detail in Chapter 50.[30,31] These methods have not been extensively validated in the setting of acute alterations in renal function, and their value for adjusting medication dosing is questionable. Additionally, these equations are complex and are not commonly used in the clinical setting.

Two other widely available markers of renal function are BUN and urine output. BUN is widely used to assess hemodialysis adequacy in chronic hemodialysis patients. However, its use in AKI is very limited because urea's production and renal clearance are heavily influenced by extrarenal factors such as critical illness, volume status, protein intake, and medications. Urine output measured over a specified period of time (e.g., 4–24 hours) allows for short-term assessment of kidney function, but its utility is limited to cases in which it is significantly decreased. The presence of anuria suggests complete kidney failure, whereas oliguria indicates some level of kidney damage. Urine output needs to be interpreted with caution, as it is dependent on several factors, such as hydration status and medications. As mentioned earlier in the chapter, a patient may have AKI and still maintain a normal urine output; this condition is referred to as nonoliguric AKI.

Another approach to measuring renal function when S_{cr} values alone are not reflective of function is to directly measure creatinine clearance over a short period of time, for example, 4 to 12 hours.[32] Although potentially precise and fairly simple to do, accuracy is questionable because the urine output is generally low, and if the collection is incomplete, the lost urine can have a dramatic impact on the clearance determination.

Currently, in addition to BUN and S_{cr}, selected blood tests, urinary chemistry, and urinary sediment are routinely used to differentiate the cause of AKI and guide patient management. For example, a complete blood cell count with differential can help rule out infectious causes of AKI. Serum electrolyte values are likely to be abnormal because of the acute decline of the kidney's ability to regulate electrolyte excretion, and particular attention should be paid to serum potassium and phosphorus values, which can be markedly elevated and cause life-threatening complications.

In individuals with normal renal function, the ratio between BUN and S_{cr} is usually less than 15:1 using conventional units (1:16 using SI units). In the presence of prerenal AKI, reabsorption of BUN exceeds that of creatinine; thus, one often sees a ratio greater than 20:1 (1:12.4). Given the limited usefulness of solely using S_{cr} or BUN concentrations to differentiate the etiology of AKI, urinary electrolytes and osmolality should be determined, and both a microscopic and chemical analysis of the urine should be performed (Table 51–5). The finding of a high urinary specific gravity, in the absence of glucosuria or mannitol administration, suggests an intact urinary concentrating mechanism and that the cause of the patient's AKI is likely prerenal azotemia. The presence of urinary protein is often difficult to interpret, especially in the setting of acute or chronic renal failure. A patient with CKD may have a baseline proteinuria, thus clouding the clinical presentation, unless this is known at the time of AKI assessment. Classically, proteinuria is a hallmark of glomerular damage. However, tubular damage can also result in proteinuria, as the tubules are responsible for reabsorbing small proteins that are normally filtered by all glomeruli. The presence of blood also results in a positive urine protein test, so this confounder must always be assessed when a positive urine protein is obtained. Hematuria suggests acute intrinsic AKI secondary to glomerular injury, infection, or a kidney stone. On microscopic examination, the key findings are cells, casts, and crystals, and the presence of one or more of these suggest specific etiologies of the AKI (Table 51–5). The presence of crystals may suggest nephrolithiasis and a postrenal obstruction. If red blood cells or red blood cell casts are present, one should consider the presence of a physical injury to the glomerulus, renal parenchyma, or vascular beds. The finding of white blood cells or white blood cell casts suggests interstitial inflammation (i.e., interstitial nephritis), which can be secondary to an allergic, granulomatous, or infectious process.

Simultaneous measurement of urine and serum electrolytes is also helpful in the setting of AKI (see Table 51–4). From these values, a

TABLE 51-5 Urinary Findings as a Guide to the Etiology of Acute Kidney Injury

Type of Urinary Evaluation	Presence of	Suggestive of
Urinalysis	Leukocyte esterases	Pyelonephritis
	Nitrites	Pyelonephritis
	Protein	
	Mild (<0.5 g/day)	Tubular damage
	Moderate (0.5–3 g/day)	Glomerulonephritis, pyelonephritis, tubular damage
	Large (>3 g/day)	Glomerulonephritis, nephrotic syndrome
	Hemoglobin	Glomerulonephritis, pyelonephritis, renal infarction, renal tumors, kidney stones
	Myoglobin	Rhabdomyolysis-associated tubular necrosis
	Urobilinogen	Hemolysis-associated tubular necrosis
Urine sediment	Microorganisms	Pyelonephritis
Cells	Red blood cells	Glomerulonephritis, pyelonephritis, renal infarction, papillary necrosis, renal tumors, kidney stones
	White blood cells	Pyelonephritis, interstitial nephritis
	Eosinophils	Drug-induced interstitial nephritis, renal transplant rejection
	Epithelial cells	Tubular necrosis
Casts	Granular casts	Tubular necrosis
	Hyaline casts	Prerenal azotemia
	White blood cell casts	Pyelonephritis, interstitial nephritis
	Red blood cell casts	Glomerulonephritis, renal infarct, lupus nephritis, vasculitis
Crystals	Urate	Postrenal obstruction
	Calcium phosphate	Postrenal obstruction

fractional excretion of sodium can be calculated. The equation for the calculation of the fractional excretion of sodium (FE_{Na}) is

$$FE_{Na} = (\text{excreted Na/filtered Na}) \times 100$$
$$= (U_{vol} \times U_{Na})/(GFR \times S_{Na}) \times 100$$

where

$$GFR = (U_{vol} \times U_{cr})/(S_{cr} \times t)$$

Thus,

$$FE_{Na} = (U_{Na} \times S_{cr} \times 100)/(U_{cr} \times S_{Na})$$

where U_{vol} is urine volume; U_{cr} is urine creatinine concentration; U_{Na} is urine sodium; S_{cr} is serum creatinine concentration; S_{Na} is serum sodium concentration, which usually does not vary much; GFR is the glomerular filtration rate; and t is the time period over which the urine is collected.

The fractional excretion of sodium is one of the better diagnostic parameters to differentiate the cause of AKI. A low urinary sodium concentration (<20 mEq/L [<20 mmol/L]) and low fractional excretion of sodium (<1%) in a patient with oliguria suggest that there is stimulation of the sodium-retentive mechanisms in the kidney and that tubular function is intact. These findings are most characteristic of prerenal azotemia. Unfortunately, diuretic use in the preceding days limits the usefulness of the fractional excretion of sodium calculation by increasing natriuresis, even in hypovolemic patients. The fractional excretion of urea (FE_{Urea}), which can be calculated like FE_{Na}, is sometimes used as an alternative means to assess tubular function.

The inability to concentrate urine results in a high fractional excretion of sodium (>2%), suggesting tubular damage is the primary cause of the intrinsic AKI. Diagnosing the type of AKI using fractional excretion of sodium is not absolute, as there are some intrinsic causes that can be associated with a low fractional excretion of sodium (e.g., contrast nephropathy, myoglobinuria, and interstitial nephritis). Highly concentrated urine (>500 mOsm/kg [>500 mmol/kg]) suggests stimulation of antidiuretic hormone and intact tubular function. These findings are consistent with prerenal azotemia.

NOVEL BIOMARKERS OF KIDNEY FUNCTION

A number of new serum and urinary biomarkers are currently under investigation for early detection and prediction of prognosis of AKI. They represent a heterogeneous group in their ability to detect, classify, and predict the clinical course of AKI. However, they all allow for a significantly earlier diagnosis of AKI compared with conventional methods, in most cases, 48 hours before a rise in S_{cr} is observed. Currently, these tests are not routinely available in most clinical practice sites. Table 51–6 summarizes the characteristics of the six most promising biomarkers that are currently under investigation.

One such marker, serum cystatin C (see Chapter 50), is an endogenous cysteine proteinase that is released into the plasma by all nucleated cells in the body at a relatively constant rate and is then freely filtered by the glomerulus.[26] It does not undergo any significant secretion or reabsorption, but is instead completely metabolized by the proximal renal tubules.[33] Thus, a reduction in GFR will result in a rise in plasma and urine concentrations of cystatin C. Cystatin C levels may be altered by certain disease states (e.g., thyroid dysfunction and systemic inflammation) and possibly patient demographics (age, weight, gender, etc.).[34–36]

Another relatively novel biomarker is neutrophil gelatinase–associated lipocalin (NGAL), a transporter protein found on cell surfaces of neutrophils and various epithelial cells. So far, NGAL has been associated with several physiologic functions, such as iron metabolism, immunity, and kidney development.[37] The 2-hour urine NGAL levels correlate well with the severity and duration of AKI and may predict length of stay, need for RRT, and death in patients undergoing cardiopulmonary bypass.[38] Although NGAL appears to be a very sensitive, specific, and early biomarker of AKI, its levels may be influenced by the presence of CKD, infection, and inflammation.[39,40] Interleukin (IL)-18, a proinflammatory cytokine, is found in elevated urinary concentrations following AKI. In fact, it seems to be specific for ischemic ATN and can distinguish it from CKD, prerenal azotemia, nephrotic syndrome, and urinary tract infections.[41] Certain systemic inflammatory and immune-mediated diseases are associated with increased plasma IL-18 levels; however, their impact on urinary IL-18 is still unknown.[40] Kidney injury molecule 1 (KIM-1) is a biomarker upregulated in the proximal tubules and released into the urine in response to ischemic and nephrotoxic ATN. One advantage of KIM-1 is that it is not expressed in healthy kidney tissue or detected in plasma. Its production may be induced by exposure to nephrotoxins and the presence of CKD.[42,43] Another novel biomarker of AKI is the liver-type fatty acid binding protein (L-FABP), which is found in proximal tubular cells and is involved in fatty acid metabolism in the kidney. Elevated urinary L-FABP levels can be found in CKD as well as in response to oxidative stress and tubulointerstitial damage.[44,45] So far, human studies have been limited but have yielded promising results.[46,47] Recently, beta trace protein (BTP), also referred to as lipocalin-type prostaglandin D synthase, has been introduced as a potential marker of GFR. BTP is a glycoprotein expressed in several tissues, most notably in cerebrospinal fluid. It catalyzes conversion of

TABLE 51-6 Summary of Selected Novel Biomarkers for Early Detection of Acute Kidney Injury

Biomarker	Sample Source	Detection Time After Surgery or Constrast Dye Administration (Hours)	Detection Time before a Change in S_{cr} Is Observed (Hours)	Advantages	Disadvantages
Cystatin C	Plasma and urine	12–14 (plasma) 6 (urine)	24–48 (plasma)	Good marker for early diagnosis of AKI Superior to S_{cr} for GFR estimation Commercial assay available Most validated (besides S_{cr})	Does not differentiate between different types of AKI Plasma levels may be influenced by thyroid dysfunction, inflammation, corticosteroids, age, gender, height, weight
NGAL	Plasma and urine	2–4 (plasma and urine)	24–72 (plasma and urine)	Good marker for early diagnosis of AKI Commercial assay available	Does not differentiate between different types of AKI Plasma levels may be influenced by CKD, inflammation, malignancy, infection
IL-18	Urine	4–12	24–48	Good marker of ischemic ATN Predictor of AKI-associated mortality	Impact of elevated serum IL-18 levels on urine levels unknown Needs further validation
KIM-1	Urine	12–24	N/A	Good marker of intrinsic AKI Predictor of AKI-associated mortality	Levels may be influenced by CKD and nephrotoxins No studies in ICU/septic patients
L-FABP	Urine	4–6	N/A	Good marker of tubulointerstitial injury	Levels may be influenced by CKD No studies in ICU/septic patients
BTP	Plasma and urine	N/A	N/A	Potentially useful marker of GFR and renal injury	Limited human studies

AKI = acute kidney injury, ATN = acute tubular necrosis, BTP = beta trace protein, CKD = chronic kidney disease, GFR = glomerular filtration rate, ICU = intensive care unit, IL-18 = interleukin-18, KIM-1 = kidney injury molecule 1, L-FABP = liver-type fatty acid binding protein, N/A = not available, NGAL = neutrophil gelatinase–associated lipocalin, S_{cr} = serum creatinine.

prostaglandin H_2 to prostaglandin D_2 and is freely filtered at the glomerulus.[48] So far, serum BTP as a marker of GFR has been studied in renal transplant recipients with good success.[49] In addition, urinary BTP may be useful in predicting renal injury in diabetic patients.[50]

DIAGNOSTIC PROCEDURES

When the source of renal injury is unclear after a history, physical examination, and assessment of laboratory values, then imaging techniques such as abdominal radiography, including the kidneys, ureters, and bladder (KUB), computed tomography (CT), and ultrasonography may be helpful. These may reveal small, shrunken kidneys indicative of CKD, and postrenal obstruction can often be identified with a renal ultrasonogram and/or CT scan. Renal ultrasonography is useful in detecting obstruction or hydronephrosis. Nephrolithiases as small as 5 nm or a narrowing of the ureteral tract can be detected by ultrasonography or more sensitive tests, such as KUB and CT. No contrast dye is required, and it is noninvasive, simple, portable, and rapid to accomplish. In selected conditions under the guidance of a nephrologist, more invasive procedures, such as cystoscopy and biopsy, may be considered to detect the presence of malignancy, prostate hypertrophy, uterine fibroids, nephrolithiases, or ureterolithiases.

If insertion of a urinary catheter into the patient's bladder after the patient has voided or attempted to void does not yield a large volume of urine (>500 mL), then one can usually exclude postrenal obstruction distal to the bladder as the cause of AKI. Cystoscopy with retrograde pyelography may be helpful if the possibility of obstruction exists, and the insertion of a catheter did not result in a significant volume of urine.

In cases in which the cause of ARF is not evident, renal biopsies are useful in determining the cause in the majority of patients. Because of the associated risk of bleeding, a renal biopsy is rarely undertaken and should only be performed in those circumstances when a definitive diagnosis is needed to guide therapy, such as the precise etiology of glomerulonephritis (see Chapter 50).

PREVENTION OF AKI

DESIRED OUTCOME

5 Given the dismal outcome of established AKI, it is critical to identify patients at risk and implement prevention strategies when possible. Once AKI occurs, treatment is largely supportive and mainly consists of removing the cause of kidney injury, minimizing subsequent complications, and allowing kidney function to recover. Consequently, the goals of AKI prevention and treatment are to (a) prevent AKI and its complications, (b) avoid or minimize further renal insults that would worsen the existing injury or delay recovery, and (c) provide supportive measures until kidney function returns.

GENERAL APPROACH TO PREVENTION

The preventive strategy will depend on the type of renal insult. Clearly, complete avoidance of all potential causes of injury is the most effective preventive method; however, it may not always be possible to implement. Sometimes, the risk of renal injury is predictable, such as decreased perfusion secondary to coronary bypass surgery or secondary to the administration of a radiocontrast dye prior to a diagnostic procedure. In these situations, the potential insult to the kidneys cannot be avoided but may be preventable with aggressive hydration and removal of any additional insults. In the outpatient setting, all healthcare professionals should educate the patient on preventive measures for AKI. Patients should receive counseling regarding their optimal daily fluid intake (~2 L/day) to avoid dehydration, especially if they are

to receive a potentially nephrotoxic medication. In the inpatient setting, hydration, maintenance of a target mean arterial pressure in the critically ill, and avoidance of nephrotoxic medications are commonly implemented strategies for the prevention of AKI.

Generally, prevention strategies are categorized into nonpharmacologic and pharmacologic therapies. It is important to recognize that the strength of supporting evidence varies between the different preventive measures described in the following sections. (See Table 51–7 for a list of proposed therapies and recommendations based on current evidence.)

NONPHARMACOLOGIC THERAPIES

Hydration

Hydration is one of the primary interventions that has consistently shown benefit and is routinely used in the prevention of AKI. Fluids have largely been studied in association with contrast-induced nephropathy (CIN), a common cause of ATN in the inpatient setting (see Chapter 55 for a detailed discussion of CIN). Typically, an increase in the S_{cr} is noted within 24 hours for CIN, peaking after 5 days. CIN is associated with increased mortality especially in individuals with CKD, diabetes, volume depletion, concurrent nephrotoxic drug therapy, or hemodynamic instability.[51] Hydration is thought to counterbalance some of the deleterious effects of radiocontrast dyes by diluting the contrast media, preventing renal vasoconstriction that contributes to hypoxia and ischemia, and minimizing tubular obstruction.[52] Current evidence supports use of isotonic saline over hypotonic saline and use of parenteral over the oral route of administration in high-risk individuals.[53,54] Sodium bicarbonate infusion has recently been evaluated for the prevention of CIN. The hypothesized mechanism for protection is that sodium bicarbonate may reduce the formation of oxygen free radicals by alkalinizing renal tubular fluid. So far, studies have produced mixed results.[55–57] Several meta-analyses have reported reduced incidences of CIN with sodium bicarbonate over isotonic saline; however, they also acknowledged that significant heterogeneity existed between studies, such as differences in the definition of CIN, cumulative dosages of sodium bicarbonate used, and study populations.[58,59] Either sodium bicarbonate or isotonic saline may be used in high-risk individuals receiving radiocontrast media. A common sodium bicarbonate regimen is 154 mEq/L (154 mmol/L) infused at 3 mL/kg/h for 1 hour before the procedure and at 1 mL/kg/h for 6 hours after the procedure.[56] The rate and duration of normal saline infusion vary, but one commonly cited regimen is 1 mL/kg/h for 12 hours before and 12 hours after the procedure.[53] The rate of administration may be adjusted depending on the patient's cardiopulmonary and volume status.

Extracorporeal Blood Purification

Another potential approach for the prevention of CIN is extracorporeal blood purification, that is, prophylactic administration of RRT to patients who are at high risk of AKI. Radiocontrast media are eliminated by the kidneys, but their clearance is delayed in patients with renal dysfunction, thereby increasing their risk for nephrotoxicity. RRT use is based on its ability to enhance radiocontrast dye clearance and thus potentially prevent nephrotoxicity. So far, studies have yielded conflicting results, some showing potential benefit, others indicating harm.[60,61] A recent meta-analysis showed no benefit of extracorporeal blood purification in decreasing the incidence of CIN.[62] In fact, there was a trend toward increased risk of harm when the analysis was limited to studies of hemodialysis. However, the meta-analysis also found that dialysis was initiated at least 1 hour after administration of the contrast media in the majority of the studies. The timing of dialysis is an important consideration, as tubular damage may start to occur after only 15 minutes of exposure to radiocontrast media.[62] Other, more practical issues associated with using prophylactic RRT are cost and the labor-intensive and invasive nature of the procedure itself.

Overall, evidence to date does not demonstrate any consistent significant benefit with the routine use of extracorporeal blood purification to prevent CIN over standard medical therapy.

PHARMACOLOGIC THERAPIES

Loop Diuretics

There is significant controversy surrounding the use of loop diuretics in the prevention of AKI. Early experimental studies proposed that loop diuretics had the following theoretical advantages: decreased risk of tubular obstruction secondary to an increased urine flow and flushing out of debris; increased urine output that may be beneficial in itself, as nonoliguric AKI is associated with better outcomes than oliguric AKI; decreased risk of ischemic injury as the result of inhibition of the sodium/potassium chloride cotransporter and thus a reduction in oxygen demand; and enhanced renal blood flow due to increased availability of renal prostaglandins.[63] However, clinical studies have been less favorable. Even though the majority of studies demonstrate that loop diuretics increase urine output, they lack beneficial effects on patient outcomes, such as mortality, need for RRT, and renal recovery.[63–65] There is even some evidence of potential harm associated with their use, in particular, ototoxicity and possibly mortality in certain clinical settings.[66] The proposed explanations for such lack of benefit are twofold. Loop diuretics may not be reaching the proximal tubule as their site of action due to tubular obstruction from debris, increased extrarenal clearance secondary to hypoalbuminemia, and increased urinary protein binding due to albuminuria. Also, loop diuretics may actually decrease renal blood flow by reducing effective circulating arterial volume, which, in turn, may stimulate the adrenergic and the renin-angiotensin systems.[63]

CLINICAL CONTROVERSY

Loop diuretics are widely used for the management of volume overload in critically ill patients, including those with concomitant AKI. Although volume overload is certainly an appropriate indication for loop diuretics, current evidence does not support their use for prevention of AKI or treatment of oliguria.

Dopamine Agonists

Dopamine is a nonselective dopamine receptor agonist that, in high doses, also stimulates the adrenergic receptors. Low doses of intravenous (IV) dopamine (≤2 mcg/kg/min) increase renal blood flow, induce natriuresis and diuresis, and might be expected to increase GFR. Theoretically, this could be considered beneficial, as an increase in renal perfusion and oxygenation might limit ischemic cell injury, inhibition of sodium transport might reduce oxygen demand, and an enhanced GFR might flush nephrotoxins and casts from the tubules. Despite these theoretical suggestions, controlled studies have found that low-dose dopamine did not prevent AKI, need for dialysis, or mortality compared with placebo.[67,68] Thus, current evidence does not support the use of low-dose dopamine for prevention of AKI.

CLINICAL CONTROVERSY

Despite most studies not showing improved patient outcomes with its use, low-dose dopamine continues to be commonly used. The risks associated with dopamine (extravasation and the potential for significant dosing errors) suggest that its use should be avoided whenever possible.

Fenoldopam mesylate is a selective dopamine A-1 receptor agonist that increases renal blood flow, natriuresis, and diueresis. Although fenoldopam seems ineffective in preventing CIN, it may have some benefit in preventing AKI in critically ill patients or those undergoing surgery.[69,70]

Antioxidants

Ascorbic Acid Ascorbic acid has mainly been studied in the prevention of CIN, as its antioxidant properties are thought to alleviate oxidative stress caused by CIN-associated ischemia reperfusion injury.[71] Studies have not consistently demonstrated benefit when ascorbic acid was given to patients with CKD for the prevention of CIN.[72,73] However, its excellent safety profile and low cost make it an attractive option for high-risk individuals. The recommended dose of ascorbic acid is 3 g orally before the procedure, then 2 g orally twice daily for two doses after the procedure.

***N*-Acetylcysteine** *N*-acetylcysteine (NAC) is another antioxidant that has been widely studied in the prevention of CIN in patients with renal insufficiency. However, a therapeutic benefit has not been consistently demonstrated, and large heterogeneity in results across different studies makes it difficult to determine whether NAC is truly effective or not.[72,74] Similar to ascorbic acid, NAC's low cost, safety profile, tolerability, and possible benefit make it a reasonable option for patients at risk for CIN. The recommended dosing regimen for prevention of CIN is 600 to 1,200 mg orally every 12 hours for four doses, with the first two doses administered prior to contrast exposure. NAC has also been evaluated for the prevention of AKI in postoperative patients, but studies have failed to demonstrate any benefit.[75,76] Thus, use of NAC should be reserved for prevention of CIN only and not for other types of AKI.

Glycemic Control

Glycemic control in critically ill patients is of utmost importance, as both hyper- and hypoglycemia are associated with increased mortality.[77] Hyperglycemia is common during critical illness, and one of its key features in that setting is insulin resistance. The causes of insulin resistance are multifactorial but include impaired glucose homeostasis due to loss of the kidney's metabolic function, as well as decreased hepatic and peripheral glucose uptake secondary to uremia. Hyperglycemia has also been associated with increased risk of renal injury, but the exact mechanisms by which glucose may contribute to renal toxicity are not fully elucidated.[78] Experimental studies indicate increased sensitivity to renal ischemia reperfusion injury, glucose overload in the kidney causing tissue damage, and increased inflammation.[79] Patients may also be at higher risk for hypoglycemia, as the kidneys are the primary metabolic site of insulin.

The target blood glucose concentrations in critically ill patients are controversial. A prospective, randomized controlled study by van den Berghe et al.[80] demonstrated a 41% reduction in the development of AKI and reduced mortality in the intensive insulin therapy group (80–110 mg/dL [4.4–6.1 mmol/L]) compared with the standard control (<200 mg/dL [<11.1 mmol/L]) group of surgical intensive care (ICU) patients. Several other studies, particularly those in nonsurgical ICU patients, failed to reproduce these results.[81,82] A recent large multicenter randomized study conducted in medical and surgical ICU patients revealed that intensive glucose control was associated with significantly greater 90-day mortality rates and higher risk of hypoglycemia compared with conventional insulin therapy (144–180 mg/dL [8–10 mmol/L]). Although the study did not report the incidence of ICU-acquired AKI, no significant difference in the need for RRT between the two groups was noted.[83] Thus, current evidence suggests that moderate control of blood glucose to levels of 144 to 180 mg/dL (8.0–10.0 mmol/L) may be more appropriate in the critical care setting. Specifically for patients with AKI, it should be recognized that they are at increased risk for hypoglycemia as well as insulin resistance due to altered renal function, so that more frequent glucose monitoring may be required.

OTHER APPROACHES TO PREVENTION

Several other therapies have been investigated for the prevention of AKI. Most of them have shown promising results in experimental studies but the experience in using them in humans is still either inconclusive or limited. One such example is theophylline, which may attenuate adenosine-mediated renal vasoconstriction and GFR reduction in patients with CIN. A systematic review of nine randomized trials indicated a trend toward reduced incidence of CIN with theophylline use. These findings require cautious interpretation as definitions of CIN as well as hydration and theophylline protocols varied markedly.[84] Thus, evidence is currently inconclusive and more research is needed to assess the role of theophylline as a modality for CIN prevention.

Erythropoietin alfa (EPO) is another agent under study for the prevention of AKI. EPO is a primary regulator of red blood cell production and is widely used to treat anemia in patients with CKD and cancer. Experimental models have demonstrated the tissue-protective role of EPO against ischemic renal injury.[85] One small prospective randomized trial has reported that a single dose of EPO (300 units/kg) significantly decreased the risk of postoperative AKI from 29% to 8% after coronary artery bypass surgery.[86] However, a recent double-blind placebo-controlled trial found no difference in the outcome of AKI among 529 enrolled ICU patients.[87] Larger clinical trials would be necessary to demonstrate its safety and efficacy before EPO can be recommended for the prevention of AKI.

Natriuretic peptides, specifically atrial natriuretic peptide (ANP) and B-type natriuretic peptide (BNP), are also being explored for the prevention of AKI in certain clinical settings. Both ANP and BNP mediate vasodilation and natriuresis, as well as increase renal perfusion and GFR. Clinical studies with anaritide (human recombinant ANP) and nesiritide have been relatively inconclusive, but there seems to be growing evidence that lower doses (50 ng/kg/min of anaritide and 0.005 μg/kg/min of nesiritide) and longer infusion

times may reduce the risk of postoperative AKI.[88,89] The proposed explanation for these differences in response is that lower doses of anaritide and nesiritide are associated with lower risks of hypotension, which, if present, may adversely affect renal perfusion and counterbalance any protective effects these drugs may have. Large multicenter, randomized studies are warranted to further clarify the role of natriuretic peptides in the prevention of AKI.

TREATMENT OF AKI

DESIRED OUTCOMES

Short-term goals include minimizing the degree of insult to the kidney, reducing extrarenal complications, and expediting the patient's recovery of renal function. The ultimate goal is to have the patient's renal function restored to his or her pre-AKI baseline.

GENERAL APPROACH TO TREATMENT

Prerenal sources of AKI should be managed with hemodynamic support and volume replacement. If the cause is immune related, as may be the case with interstitial nephritis or glomerulonephritis, appropriate immunosuppressive therapy must be promptly initiated. Postrenal therapy focuses on removing the cause of the obstruction. It is important to approach the treatment of established AKI with an understanding of the patient's comorbidities and baseline renal function. Loss of kidney function combined with other clinical conditions, such as cardiac and liver failure, are associated with higher mortality than that associated with the development of AKI alone.[90] At times, the most efficacious remedy for AKI is management of the comorbid precipitating event. Appreciation of the baseline renal function is also important at the outset of AKI management, because the presence of CKD indicates the highest degree of renal function that can be attained after AKI resolution. Finally, the presence of CKD indicates that the kidneys have less reserve; thus, there is a greater likelihood that the individual may not fully recover from the current insult.

6 Supportive care is the mainstay of AKI management regardless of etiology. RRT may be necessary to maintain fluid and electrolyte balance while removing accumulating waste products. The slow process of renal recovery cannot begin until there are no further insults to the kidney. In the case of ATN, the recovery process typically occurs within 10 to 14 days after resolution of the last insult. The recovery period will be prolonged if the kidney is exposed to repeated insults.

NONPHARMACOLOGIC

Initial modalities to reverse or minimize prerenal AKI include eliminating medications associated with diminished renal blood flow, improving cardiac output, and removing a prerenal obstruction. If dehydration is evident, then appropriate fluid replacement therapy, as described later in this chapter, should be initiated. Moderately volume-depleted patients can be given oral rehydration fluids; however, if IV fluid is required, isotonic normal saline is the replacement fluid of choice, and large volumes may be necessary to provide adequate fluid resuscitation. Typically, IV fluid challenges are initiated with 250 to 500 mL of normal saline over 15 to 30 minutes with an assessment after each challenge of the patient's volume status. Unless profound dehydration is present, as may be seen in diabetic ketoacidosis and hyperosmolar hyperglycemic states, 1 to 2 L is usually adequate. Patients with diabetic ketoacidosis or a hyperosmolar hyperglycemic state often have a 10% to 15% total-body water deficit, and more aggressive fluid replacement is necessary. The patient should be monitored for pulmonary edema, peripheral edema, adequate blood pressure (diastolic blood pressure >60 mm Hg), normoglycemia, and electrolyte balance. Urine output may not be promptly observed, as the kidney continues to retain sodium and water until rehydration is achieved. Up to 10 L may be required in the septic patient during the first 24 hours, because of the profound increase in vascular capacitance and fluid leakage into the extravascular, interstitial space.[91]

Patients with AKI on top of preexisting CKD should not be expected to produce urine beyond their preexisting baseline. In patients with anuria or oliguria, slower rehydration, such as 250 mL boluses or 100 mL/h infusions of normal saline, should be considered to reduce the risk for pulmonary edema, especially if heart failure or pulmonary insufficiency exists. Other replacement fluids may be considered if the dehydration is accompanied by a severe electrolyte imbalance amenable to large and relatively rapid infusions. For example, dehydration resulting from severe diarrhea is often accompanied by metabolic acidosis caused by bicarbonate losses. A reasonable IV rehydration fluid in this situation is 5% dextrose with 0.45% sodium chloride (NaCl) plus 50 mEq (50 mmol) of sodium bicarbonate per liter, administered as boluses as described above, followed by a brisk continuous infusion (200 mL/h) until rehydration is complete, acidosis corrected, and diarrhea resolved. This fluid will remain mostly in the intravascular space, providing the necessary perfusion pressure to the kidneys, as well as a substantial amount of bicarbonate to correct the acidosis.

If the prerenal AKI is a result of blood loss or is complicated by symptomatic anemia, red blood cell transfusion to a hematocrit no higher than 30% is the treatment of choice.[92] Although albumin is sometimes used as a resuscitative agent, its use should be limited to individuals with severe hypoalbuminemia (e.g., liver disease and nephritic syndrome) who are resistant to crystalloid therapy. These patients have severe hypoalbuminemia-associated third spacing that complicates fluid management, and albumin may be useful in this setting.

The most common interventions that must be made when treating patients with intrinsic or postobstructive AKI involve fluid and electrolyte management. Most patients with these types of AKI, as well as those with a prerenal cause who are excessively fluid resuscitated, ultimately become fluid overloaded. This means drug infusions and nutrition solutions must be maximally concentrated. So-called keep vein open or maintenance IV infusions should be minimized unless the patient is euvolemic or is receiving RRT to maintain fluid balance. Supportive care goals for the hospitalized patient with any type of AKI include maintenance of adequate cardiac output and blood pressure to allow adequate tissue perfusion. However, a fine balance must be maintained in anuric and oliguric patients unless the patient is hypovolemic or is able to achieve fluid balance via RRT. If fluid intake is not minimized, edema may rapidly develop, especially in hypoalbuminemic patients. In contrast, a continuous IV infusion of vasopressors, such as dopamine, at doses of ≥2 mcg/kg/min, or norepinephrine when used to maintain adequate tissue perfusion, may also induce kidney hypoxia as the result of a reduction in renal blood flow. Consequently, hemodynamic monitoring may be necessary for critically ill patients (see Chapter 30).

Because there is no current definitive therapy for AKI, supportive management remains the primary approach to prevent or reduce associated complications or death. In the presence of severe AKI, RRTs are commonly prescribed to manage uremia, metabolic acidosis, hyperkalemia, and complications of excess fluid retention, such as pulmonary edema and accumulation of renally cleared medications. Although precise indications for starting RRT are unclear, some general guidelines for therapy have been proposed (Table 51–8).

TABLE 51-8 The AEIOUs That Describe the Indications for Renal Replacement Therapy

Indication for Renal Replacement Therapy	Clinical Setting
A Acid–base abnormalities	Metabolic acidosis resulting from the accumulation of organic and inorganic acids
E Electrolyte imbalance	Hyperkalemia, hypermagnesemia
I Intoxications	Salicylates, lithium, methanol, ethylene glycol, theophylline, phenobarbital
O fluid overload	Postoperative fluid gain
U Uremia	High catabolism of acute renal failure

Renal Replacement Therapies

7 RRTs can be administered either intermittently or continuously. The optimal mode for hemodialysis is unclear and varies depending on the clinical presentation of the patient.[93] Some recent data suggest that more aggressive approaches using RRTs in a more liberal fashion or use of a bioartificial membrane consisting of renal proximal tubule cells may improve survival in critically ill patients with AKI.[93,94] The choice of continuous versus intermittent RRTs is a matter of considerable debate and is usually determined by physician preference and the resources available at the hospital.

Intermittent Hemodialysis

Intermittent hemodialysis (IHD) is the most frequently used RRT and has several advantages. IHD machines are readily available in most acute care facilities, and healthcare workers are commonly familiar with their use. Hemodialysis treatments usually last 3 to 4 hours, with blood flow rates to the dialyzer typically ranging from 200 to 400 mL/min. Advantages of IHD include rapid removal of volume and solute and rapid correction of most of the electrolyte abnormalities associated with AKI. IHD can be scheduled at times that maximize staffing availability and treatments per day per machine, while minimizing inconvenience to the patient. The primary disadvantage is hypotension, typically caused by rapid removal of intravascular volume over a short period of time. Venous access for dialysis can be difficult in hypotensive patients and can limit the effectiveness of IHD, leading to ineffective solute clearance, lack of acidosis correction, continued volume overload, and delayed recovery because of further renal ischemia insults. If hemodialysis is carefully monitored and hypotension avoided, better patient outcomes can be achieved.[95] Patients with stage 5 CKD generally achieve adequate solute and volume control with dialysis done three times weekly, but hypercatabolic, fluid-overloaded patients with AKI may require daily hemodialysis treatments.[96] The use of daily versus three times weekly IHD in the setting of AKI has been associated with a reduction in dialysis-related hypotension and a shorter period of time to full recovery of kidney function.[97] Chapter 54 provides a detailed explanation of the principles and processes of hemodialysis.

Continuous Renal Replacement Therapies

In contrast to IHD, CRRTs that were developed over the past 15 years have proven to be a viable management approach for hemodynamically unstable patients with AKI.[98] Several CRRT variants have been developed, including continuous venovenous hemofiltration (CVVH), continuous venovenous hemodialysis (CVVHD), and continuous venovenous hemodiafiltration (CVVHDF). They differ in the degree of solute and fluid clearance that can be clinically achieved as a result of the use of diffusion, convection, or a combination of both. Although solute removal is slower, a greater amount can be removed over a 24-hour period compared with IHD, which is associated with improved outcomes in critically ill patients with AKI.[99]

In CVVH, solute and fluid clearance is primarily a result of convection, in which passive diffusion of fluids containing solutes is removed, while volume absent of the solutes is replaced (Fig. 51–4). CVVHD provides extensive solute removal primarily by diffusion, in which solute molecules at a higher concentration (plasma) pass through the dialysis membrane to a lower concentration (dialysate), and some fluid is removed as a function of the ultrafiltration coefficient of the dialyzer. Because the dialysate flows in a countercurrent direction to the plasma flow on the other side of the membrane, the concentration gradient is maximized. CVVHD is associated with a lower incidence of clotting than CVVH because of reduced hemoconcentration, as there is less fluid removal during the process. CVVHDF combines both convection or hemofiltration and hemodialysis, achieving even higher solute and fluid removal rates (Fig. 51–4). The ultrafiltration rate is an important determinant of the effectiveness of all three forms of CRRT; achievement of a removal rate of 35 mL/kg/h is associated with improved survival.[99] However, in direct comparisons of ultrafiltration rates of 25 to 40 mL/kg/h or higher, no difference in mortality has been observed, and there was a tendency toward prolonged need for renal replacement in those who received the higher ultrafiltration rate.[100,101]

Because of the reduced blood flow rates relative to IHD, thrombosis is a significant concern with CRRT; thus, some form of anticoagulation during RRT is generally necessary for almost all patients. Typical anticoagulation is achieved by the administration of unfractionated heparin, or in some cases, a low molecular weight heparin, direct thrombin inhibitor, or citrate solution.[102] Replacement fluids can be infused either just before or after the dialyzer/hemofilter. Infusing fluids after the hemofilter can result in hemoconcentration within the filter, a factor associated with an increased risk of thrombosis of the dialyzer. Replacing fluids before the filter reduces thrombosis risk, but it also reduces solute clearance.

Disadvantages of CRRT are that not all hospitals have the special equipment necessary to provide these treatments, they require intensive nursing care around the clock, and they are more expensive than IHD because of the need to individualize the IV replacement and dialysate fluids. There is also very little known about drug-dosing requirements for those who are receiving these therapies.[103] CRRT use is most commonly considered for those patients with higher acuity because of their intolerance of IHD-associated hypotension. In one meta-analysis, no difference in clinical outcomes between the two approaches was seen until there was an adjustment for severity of illness. CRRT was then found to be associated with a lower mortality rate.[104] Because patients treated with continuous therapies are almost always more critically ill than those treated by IHD, comparisons of outcome must control for illness severity.

CRRT and hybrid extended-duration intermittent hemodialysis are now being commonly used for critically ill patients with AKI. With CRRT, more solute and water removal can be achieved than with the hemodialysis treatments given three times per week for patients with ESKD. This has influenced how dialysis is prescribed in the intensive care unit for hypercatabolic patients with AKI. Daily IHD is associated with improved survival and faster resolution of AKI compared with dialysis given every other day.[90] Daily delivery of IHD presents challenges to clinicians prescribing drug and nutrition therapy, as most of these dosing guidelines are based on dialysis given three times per week in CKD patients. Thus, application of these guidelines in patients with AKI may yield suboptimal outcomes.

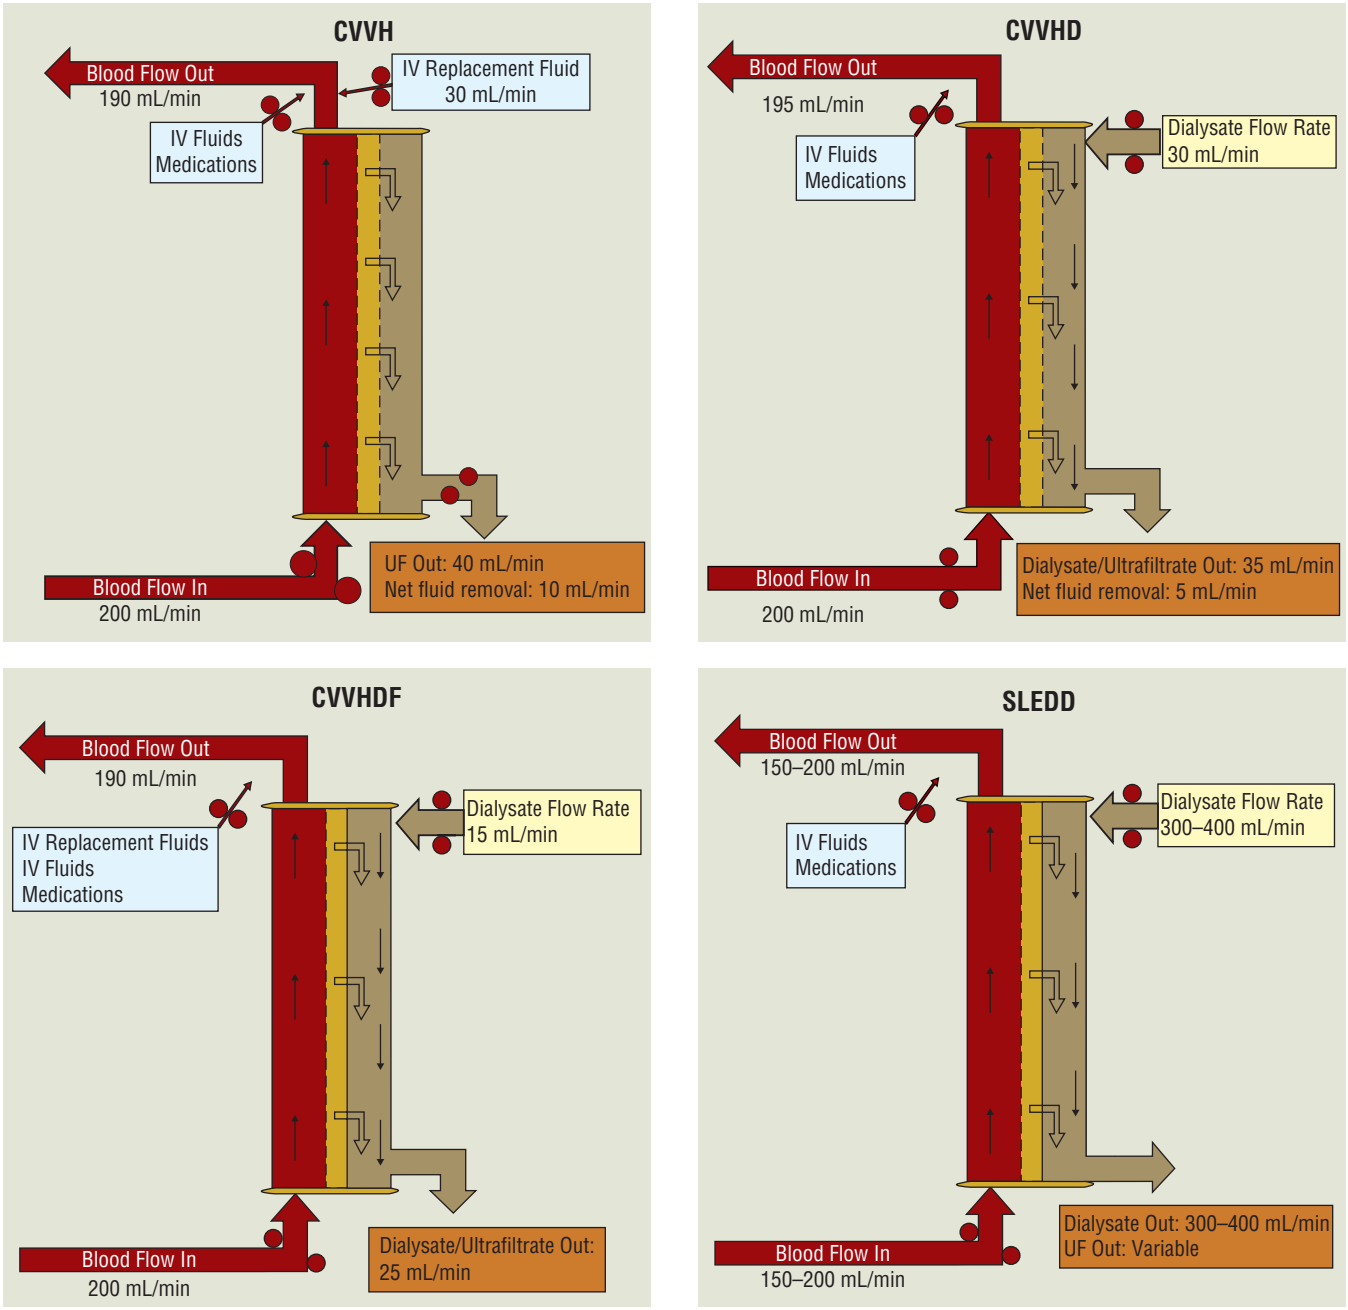

FIGURE 51-4. Several renal replacement therapies are commonly used in patients with AKI, including one of the three primary continuous renal replacement therapy (CRRT) variants: (a) continuous venovenous hemofiltration (CVVH), (b) continuous venovenous hemodialysis (CVVHD), (c) continuous venovenous hemodiafiltration (CVVHDF), and the hybrid intermittent hemodialysis therapy (d) slow extended daily dialysis (SLEDD). The blood circuit in each diagram is represented in red, the hemofilter/dialyzer membrane is yellow, and the ultrafiltration/dialysate compartment is brown. Excess body water and accumulated endogenous waste products are removed solely by convection when CVVH is employed. With CVVHD, waste products are predominantly removed as the result of passive diffusion from the blood, where they are in high concentration to the dialysate. The degree of fluid removal that is accomplished by convection is usually minimal. CVVHDF uses convection to a degree similar to that employed during CVVH as well as diffusion, and thus is often associated with the highest clearance of drugs and waste products. Finally, SLEDD employs lower blood and dialysate flow rates than intermittent hemodialysis (IHD), but because of its extended duration, it is a gentler means of achieving adequate waste product and fluid removal.

Hybrid IHD therapies have a variety of names, with the two most common being sustained low-efficiency dialysis[105] and slow, extended, daily dialysis (see Fig. 51–4).[106] These therapies use lower blood (150–200 mL/min) and dialysate (300–400 mL/min) flow rates with extended treatment periods of 6 to 12 hours. Unlike CRRT, these therapies do not require any new equipment. Anticoagulation is still required, but the amount necessary compared with CRRT is lower.[106] Although the use of hybrid hemodialysis therapies is increasing, our knowledge of the impact of these therapies on drug removal remains limited.[107,108]

CLINICAL CONTROVERSY

Some clinicians believe that CRRTs are preferable to IHD because they provide more consistent fluid and waste product removal. Others suggest that IHD is preferable because the nursing and medical staff is more familiar with its use, and round-the-clock nursing is not needed. New hybrid approaches with slower removal over a prolonged time period may potentially appeal to both groups.

PHARMACOLOGIC

Once the kidney has been damaged by an acute insult (e.g., reduced perfusion or exposure to exogenous or endogenous nephrotoxins), initial therapies should be directed to prevent further insults to the kidney, thereby minimizing extension of the injury.[109] If sepsis is present, antibiotic therapy regimens should be adjusted for decreased renal elimination, the potential for increased elimination if the agent is removed by hemodialysis, and the ability to treat the infection to prevent further damage to the kidney. The time to recovery from AKI is determined from the most recent insult to the kidney, not the first insult. Hospitalized patients with AKI are at high risk for repeated episodes of kidney injury as the result of repeated exposures to nephrotoxic agents and hypotensive episodes, among other problems. These increased risks, coupled with the fact that no drugs have been found to accelerate AKI recovery, dictate the way clinicians approach the AKI patient.

To date, no pharmacologic approach to reverse the decline or accelerate the recovery of renal function has been proven to be clinically useful. Many agents have looked promising in animal trials, only to be found ineffective in human trials. Numerous agents have been investigated and shown no benefit in the treatment of established AKI.[110] In recent years thyroxine,[111] dopamine,[67,112] and loop diuretics[113–115] have all been documented either to be of no help or to worsen patient outcomes. For example, a 77% increase in mortality or nonrecovery of renal function was reported in patients with AKI who received a loop diuretic compared with patients who did not receive loop diuretics.[115] These findings may be explained by the fact that sicker, fluid-overloaded patients may be more likely to receive diuretics; nonetheless, no benefit to loop diuretic use could be found in any subanalysis. Consequently, loop diuretic use should be reserved for fluid-overloaded patients who make adequate urine in response to diuretics to merit their use.[113] Prevention of pulmonary edema is an important goal, and it is preferable that it be accomplished with diuretics instead of more invasive RRTs, despite the previously mentioned finding that diuretic use may be associated with diminished outcomes.[115] The most effective drugs in producing diuresis in the patient with AKI, mannitol and the loop diuretics, have distinct advantages and disadvantages. Mannitol, which works as an osmotic diuretic, can only be given parenterally. A typical starting dose is mannitol (20%) 12.5 to 25 g infused intravenously over 3 to 5 minutes. It has little nonrenal clearance, so when given to anuric or oliguric patients, mannitol will remain in the patient, potentially causing a hyperosmolar state. Additionally, mannitol may cause AKI itself, so its use in AKI must be monitored carefully by measuring urine output and serum electrolytes and osmolality.[116] Adequately designed comparative trials of mannitol to normal saline currently do not exist. Because of these limitations of mannitol, some clinicians recommend that it be reserved for the management of cerebral edema.[117]

Furosemide and bumetanide are the most frequently used loop diuretics in patients with AKI. Ethacrynic acid is typically reserved for patients who are allergic to sulfa compounds. Furosemide is the most commonly used loop diuretic because of its lower cost, availability in oral and parenteral forms, and reasonable safety and efficacy profiles. A disadvantage with furosemide is its variable oral bioavailability in many patients and potential for ototoxicity with high serum concentrations that may be attained with rapid, high-dose bolus infusions. Consequently, initial furosemide doses, which should not exceed 40 to 80 mg, are usually administered intravenously to assess whether the patient will respond. Torsemide and bumetanide have better oral bioavailability than furosemide and are more potent; 4:1 and 40:1 respectively compared to furosemide. Torsemide has a longer duration of activity than the other loop diuretics, which allows for less-frequent administration but which also may make it more difficult to titrate the dose. Loop diuretics all work equally well provided that they are administered in equipotent doses. In a patient who is unresponsive to aggressive IV loop diuretic therapy, switching to another loop diuretic is unlikely to be beneficial.

TABLE 51-9 Common Causes of Diuretic Resistance in Patients with Severe AKI

Causes of Diuretic Resistance	Potential Therapeutic Solutions
Excessive sodium intake (sources may be dietary, IV fluids, and drugs)	Remove sodium from nutritional sources and medications
Inadequate diuretic dose or inappropriate regimen	Increase dose, use continuous infusion or combination therapy
Reduced oral bioavailability (usually furosemide)	Use parenteral therapy; switch to oral torsemide or bumetanide
Nephrotic syndrome (loop diuretic protein binding in tubule lumen)	Increase dose, switch diuretics, use combination therapy
Reduced renal blood flow	
Drugs (NSAIDs, ACEIs, vasodilators)	Discontinue these drugs if possible
Hypotension	Intravascular volume expansion and/or vasopressors
Intravascular depletion	Intravascular volume expansion
Increased sodium resorption	
Nephron adaptation to chronic diuretic therapy	Combination diuretic therapy, sodium restriction
NSAID use	Discontinue NSAID
Heart failure	Treat heart failure, increase diuretic dose, switch to better-absorbed loop diuretic
Cirrhosis	High-volume paracentesis
Acute tubular necrosis	Higher dose of diuretic, diuretic combination therapy; add low-dose dopamine

ACEIs = angiotensin-converting enzyme inhibitors, IV = intravenous, NSAIDs = nonsteroidal antiinflammatory drugs.

Diuretic Resistance

8 The inability to respond to administered diuretics is common in AKI and is associated with a poor patient outcome (Table 51–9).[115] An effective technique to overcome diuretic resistance is to administer loop diuretics via continuous infusions instead of intermittent boluses. Less natriuresis occurs when equal doses of loop diuretics are given as a bolus instead of as a continuous infusion. Furthermore, adverse reactions from loop diuretics (myalgia and hearing loss) occur less frequently in patients receiving continuous infusion compared with those receiving intermittent boluses, ostensibly because higher serum concentrations are avoided. However, these adverse effects still may occur with continuous infusion of loop diuretics and should be monitored.[118] The finding that the continuous infusions of loop diuretics have efficacy that is at least as good as intermittent bolus dosing, with fewer adverse effects, appears to be consistent for all agents, including furosemide,[119] bumetanide,[120] and torsemide.[121] When a continuous loop diuretic infusion is used, an initial loading dose is given (equivalent to furosemide 40–80 mg) prior to the initiation of a continuous infusion at 10 to 20 mg/h of furosemide or its equivalent. Patients with low creatinine clearances may have much lower rates of diuretic secretion into the tubular fluid; consequently, higher doses are generally used in patients with renal insufficiency.[117] Diuretic resistance may occur simply because excessive sodium intake overrides the ability of the diuretics to eliminate sodium. However, other reasons for diuretic resistance often exist in this population. Patients with ATN have a reduced number of functioning nephrons on which the diuretic may exert

its action. Other clinical states, such as glomerulonephritis, are associated with heavy proteinuria. Intraluminal loop diuretics cannot exert their effect in the loop of Henle because they are extensively bound to proteins present in the urine. Still other patients may have greatly reduced bioavailability of oral furosemide because of intestinal edema, often associated with high preload states, which further reduces oral furosemide absorption. Table 51–9 includes possible therapeutic options to counteract each form of diuretic resistance. Combination therapy of loop diuretics plus a diuretic from a different pharmacologic class may be an alternative approach in the setting of AKI.[122] Loop diuretics increase the delivery of NaCl to the distal convoluted tubule and collecting duct. With time, these areas of the nephron compensate for the activity of the loop diuretic and increase sodium and chloride resorption. Diuretics that work at the distal convoluted tubule (chlorothiazide and metolazone) or the collecting duct (amiloride, triamterene, and spironolactone) may have a synergistic effect when administered with loop diuretics by blocking the compensatory increase in sodium and chloride resorption. The combination of loop diuretics and usual doses of thiazide diuretics may be effective in renal disease despite the accumulation of endogenous organic acids in renal disease that blocks the transport of loop diuretics into the lumen. If oral thiazides cannot be given to the patient, chlorothiazide 500 mg, a more expensive option, can be administered parenterally.

Several drug combinations with loop diuretics have been investigated, including the addition of one or more of the following: theophylline, acetazolamide, spironolactone, thiazides, or metolazone.[116] Of these combinations, oral metolazone is used most frequently with furosemide. Metolazone, unlike other thiazides, produces effective diuresis at a GFR <20 mL/min (0.33 mL/s). This combination of metolazone and a loop diuretic has been used successfully in the management of fluid overload in patients with heart failure, cirrhosis, and nephrotic syndrome. Despite a lack of supporting evidence, oral metolazone at a dose of 5 mg is commonly administered 30 minutes prior to an IV loop diuretic to allow time for absorption. Additionally, this combination has been found to be efficacious in pediatric patients in addition to adults.[123] The combination of mannitol plus IV loop diuretics is used by some practitioners,[124] but no convincing evidence of the superiority of this combination regimen to conventional dosing of either diuretic alone exists.

ELECTROLYTE MANAGEMENT

Hypernatremia and fluid retention are frequent complications of AKI; thus, sodium restriction is a necessary intervention. In general, patients should receive no more than 3 g of sodium per day from all sources, including IV fluids, drugs, and enteral intake. Clinicians should be vigilant about sources of sodium. Excessive sodium intake is a common reason diuretic therapy fails. Commonly administered IV antibiotics, as well as other medications, may contain significant amounts of sodium; for example, 1 L of 0.9% NaCl yields 154 mEq (154 mmol; 3.5 g) of sodium. At usual doses, IV metronidazole provides 1.3 g of sodium per day, ampicillin up to 800 mg, piperacillin ~700 mg, and fluconazole 500 mg. The cumulative effect of a few sodium-containing medications and fluids can be significant.

In continuous and intermittent RRTs, there usually is less concern about hyponatremia developing because these therapies often incorporate isonatremic (135–140 mEq/L [135–140 mmol/L] of sodium) solutions as the dialysate or ultrafiltrate replacement solutions. Serum sodium concentrations should be monitored daily. Hyperkalemia, hyperphosphatemia, and, to a lesser extent, hypermagnesemia are electrolyte disorders that are frequently seen in patients with AKI. Higher ultrafiltration rates can potentially increase the risk for hyperphosphatemia. The shift in electrolytes is generally not a serious concern in those who are receiving RRT, but electrolytes should be monitored closely in all patients with AKI.

The most common electrolyte disorder encountered in AKI patients is hyperkalemia, as >90% of potassium is renally eliminated. Life-threatening cardiac arrhythmias may occur with serum potassium concentrations >6 mEq/L (6 mmol/L), so potassium restriction is essential. All patients with AKI should have serum potassium monitored at least daily, and twice daily for those who are seriously ill. This frequency is a consequence of the seriousness of the potential arrhythmias, the dynamic nature of potassium serum concentrations in the acutely ill patient, the potential for metabolic acidosis leading to increased extracellular potassium concentrations, and potassium's ubiquitous presence in foods and some medications. Commonly encountered medications that contain substantial amounts of potassium include oral phosphorous replacement powders (e.g., Neutra-Phos and Neutra-Phos-K) and alkalinizers (Polycitra) (see Chapter 59). Many foods are high in potassium, including potatoes, beans, and various fruits. Some medications may promote potassium retention by the kidneys and should also be avoided or closely monitored (see Chapter 55 and 60). Typically, no potassium should be added to parenteral solutions unless hypokalemia is documented. Patients receiving enteral nutrition should be limited to a 3 g potassium diet. Patients receiving RRT should also have their serum potassium concentration measured at least daily. Some centers add no potassium to their CRRT solutions, and hypokalemia can result unless one is prospectively monitoring for its development. Chapter 60 discusses the treatment of hyperkalemia in detail.

Other electrolytes that require monitoring are phosphorus and magnesium. Both are eliminated by the kidneys and are not removed efficiently by dialysis. In the early stages of AKI, hyperphosphatemia may be more common than hypophosphatemia. Patients who have significant tissue destruction (e.g., trauma, rhabdomyolysis, and tumor lysis syndrome) may have significant phosphorus released from the destroyed tissue. Treatment of the hyperphosphatemic state can include CRRT. Calcium-containing antacids should be avoided to prevent precipitation of calcium phosphate in the soft tissues. Typically, the dietary intake of phosphorus and magnesium is restricted, but in patients receiving prolonged renal replacement, deficiency states can occur, particularly in pediatric patients because of their reduced body stores. In contrast to the patient with CKD, calcium balance is usually not an important issue for the patient with AKI because of the limited duration of the illness. One exception to this is seen in patients who are receiving CRRT with citrate as the anticoagulant. Citrate binds to serum calcium, and without an adequate concentration of calcium, blood cannot form a clot. Citrate is thus typically infused before the dialyzer/hemofilter to maintain the dialyzer circuit calcium levels between 0.70 and 1 mEq/L (0.35–0.50 mmol/L). Calcium chloride (10 g of CaCl diluted in 500 mL normal saline) or gluconate (20 g of calcium gluconate to 500 mL normal saline) is then administered prior to returning the blood to the patient to maintain systemic ionized calcium levels between 2.22 and 2.62 mEq/L (1.11–1.31 mmol/L).[125] The citrate that reaches the systemic circulation is subsequently metabolized by the liver. Severe hypocalcemia can result in arrhythmias, even death, so frequent monitoring of unbound serum calcium concentrations is essential.

NUTRITIONAL INTERVENTIONS

Nutritional management of critically ill patients with AKI can be extremely complex, as it needs to account for metabolic derangements resulting from both renal dysfunction and underlying disease processes, as well as the effects of RRT on nutrient balance. Stress,

inflammation, and injury lead to hypermetabolic and hypercatabolic states and may alter the nutritional requirements. In addition, severe malnutrition found in up to 42% of patients with AKI is a risk factor for increased hospital mortality and length of stay.[126] Thus, patient outcomes can be significantly improved if the nutritional status is optimized (see Chapter 153).

Loss of the normal physiologic and metabolic functions of the kidney and the hypercatabolic response to stress and injury will have a significant impact on the metabolism of nutrients. Derangements in glucose, lipid, and protein metabolism result in hyperglycemia and insulin resistance, hypertriglyceridemia, and protein catabolism and negative nitrogen balance (see Chapter 153 for a detailed discussion). The latter, in particular, is problematic to manage, as increased amino acid turnover and skeletal muscle breakdown lead to muscle wasting and malnutrition and do not respond well to increasing exogenous protein supplementation. CRRT is often employed in this patient population to help manage complications such as fluid overload, electrolyte abnormalities, and azotemia. However, CRRT may also remove small water-soluble molecules such as amino acids and certain micronutrients. As a result, patients receiving CRRT will typically have higher protein requirements (1.5–2.5 g/kg/day) and may require additional micronutrient supplementation to account for these losses. The degree of amino acids lost through CRRT depends on the type and modality of CRRT used, duration of dialysis, dialysate flow rate, effluent rate, and type of hemodiafilter membrane.[127]

Another nutritional consideration for patients receiving CRRT is the heat loss as a consequence of the cooling of the patient's blood as it traverses the extracorporeal circuit.[128] Even though the blood cooling effect by CRRT is widely recognized in clinical practice, its prevention and effect on energy and nutritional requirements have not been well studied. Limited research on CRRT-induced hypothermia is difficult to compare because of inconsistencies in the definition of hypothermia, as well as differences in types, modalities, and circuit configurations used. It has been proposed that the heat loss can be attenuated by warming the IV ultrafiltrate replacement solution, but other investigators found no benefit in using fluid warmers to prevent CRRT-induced hypothermia.[129] The blood-cooling effect is reported to occur more frequently with venovenous modalities, higher dialysate, and lower blood flow rates. Also, certain patient characteristics, such as female gender, low normal baseline temperature, and low body weight, have been identified as risk factors for hypothermia.[128,129] In summary, CRRT should be recognized as a potential source of heat loss. However, no recommendations are currently available for prevention or define the nutritional supplementation that may be necessary as the result of CRRT-induced blood cooling.

DRUG-DOSING CONSIDERATIONS

9 Optimization of drug therapy for patients with AKI is often quite challenging. The multiple variables influencing responses to the drug regimen include the patient's residual drug clearance, the accumulation of fluids, which can markedly alter a drug's volume of distribution, and delivery of CRRT or IHD, which can increase drug clearance and affect the patient's fluid status to further complicate the clinician's projection of the optimal dosage regime. For renally eliminated drugs (>30% excreted unchanged in the urine), particularly for agents with a narrow therapeutic range, serum drug concentration measurements and assessment of pharmacodynamic responses are likely to be necessary. If hepatic function is intact, choosing an agent eliminated primarily by the liver may be preferred. However, any renally eliminated active metabolites may accumulate to a point where they can elicit an undesired pharmacologic effect. Renal failure can also independently impair nonrenal drug elimination that includes metabolism.[130] Clinical experiences and pharmacokinetic studies in patients with established AKI are fairly limited. The use of dosing guidelines based on data derived from patients with stable CKD, however, may not reflect the clearance and volume of distribution in critically ill AKI patients (see Chapter 57).[103,131]

CLINICAL CONTROVERSY

In the volume-depleted patient requiring a renally eliminated medication, dosing regimens based on the initial S_{cr} prior to fluid therapy have the potential to underestimate renal function and drug elimination, resulting in subtherapeutic serum concentrations. Although not accepted as a standard practice, an initial 24-hour dosing regimen with a bolus might be optimal for many patients.

Edema, which is common in AKI, can significantly increase the volume of distribution of many drugs, particularly water-soluble ones with relatively small volumes of distribution. Increased fluid distribution into the tissues (i.e., sepsis and anasarca in heart failure) can also contribute to a larger volume of distribution for many drugs and thereby reduce the proportion of drug in the plasma that is available to be removed by CRRT or IHD. Because AKI frequently occurs in critically ill patients, multisystem organ failure is often an accompanying problem. Reductions in cardiac output or liver function in addition to volume overload can significantly alter the pharmacokinetic profile of many drugs, such as vancomycin, aminoglycosides, and low molecular weight heparins.[132,133]

In almost all cases where rapid onset of activity is desired, a loading dose may be necessary to promptly achieve desired serum concentrations because the expanded volume of distribution and the prolonged elimination half-life result in an extended time (3.5 times the half-life) until steady-state concentrations are achieved. Maintenance dosing regimens should be reassessed frequently and be based on the patient's current renal function. A dose that provides the desired serum concentration on one day may be inappropriate only a few days later if the patient's fluid status, RRT prescription or renal function has changed dramatically.

CLINICAL CONTROVERSY

Some clinicians use a standard ESKD dosage regimen despite the fact that renal function can fluctuate, such that the patient's renal function may be in one dosing range one day and in another the next. Others believe, however, that the patient's clinical need for the drug and any change in the volume of distribution or the RRT therapy should be considered if one has any chance of achieving the target serum concentrations.

Drug therapy individualization for the AKI patient who is receiving any form of renal replacement therapy is complicated by the fact that patients with AKI may have a higher residual nonrenal clearance than patients with CKD who have a similar CL_{cr}.[103] This has been reported with some drugs, such as ceftriaxone, imipenem, and vancomycin.[134–138] Alterations in the activity of some, but not

all, cytochrome P450 enzymes have been demonstrated in patients with CKD.[130] The nonrenal clearance of imipenem in patients with AKI (91 mL/min [1.52 mL/s]) is between the values observed in stage 5 CKD patients (50 mL/min [0.84 mL/s]) and those with normal renal function (120 mL/min [2 mL/s]).[138] This may be the result of less accumulation of uremic waste products that may alter hepatic function. A nonrenal clearance value in a patient with AKI that is higher than anticipated based on data from individuals with CKD would result in lower than expected, possibly subtherapeutic, serum concentrations. For example, to maintain comparable serum concentrations, the imipenem dose requirement in patients with AKI would be 2,000 mg daily as compared with the recommended dosage for patients with ESKD of 1,000 mg daily.[138] As AKI persists, the nonrenal clearance values appear to approach those observed in patients with CKD.[136,138,139] Finally, the clearance of aminoglycosides has been reported to be higher and the elimination half-life shorter in those with severe AKI compared with ESKD patients requiring hemodialysis.[131] Another challenge is that much of the dosing-related data was acquired in patients with CKD, with initial pharmacokinetic assessments done after single-dose administration. The determination of pharmacokinetic parameters using a single-dose model may result in more rapid initial drug removal estimates secondary to distribution from the plasma to the tissue as well. Thus, application of dosing regimens derived from studies in patients with CKD and ESKD may result in underdosing of these agents and thereby contribute to less than optimal clinical outcomes.

IHD Compared with CRRT

In addition to patient-specific differences, there are marked differences between IHD and the three primary types of CRRT—CVVH, CVVHD, and CVVHDF—with regard to drug removal.[140–142]

CRRT During CVVH, drug removal primarily occurs via convection/ultrafiltration (the passive transport of drug molecules at the concentration at which they exist in plasma water into the ultrafiltrate). Convective removal is most efficient for smaller agents, typically less than 15,000 Da (15 kDa) in size, and those that are primarily unbound in the plasma. The clearance of a drug by either of these methods is thus a function of the membrane permeability for the drug, which is called the sieving coefficient (SC) and the rate of ultrafiltrate formation (UFR). Alteration in the pore size of the filter and surface charge relative to the molecule being removed may vary between different dialyzers. If diffusion of the drug is not dependent on the filter pore size, then the SC can be calculated as follows:

$$SC = (2 \times C_{UF})/[(C_a) + (C_v)]$$

where C_a and C_v are the concentrations of the drug in the plasma going into and returning from the dialyzer/hemofilter, respectively, and C_{UF} is the concentration in the ultrafiltrate. The SC is often approximated by the fraction unbound (f_u) because this information may be more readily available. Thus, the clearance by CVVH can be calculated as

$$Cl_{CVVH} = UFR \times SC$$

or approximated as

$$Cl_{CVVH} = UFR \times f_u$$

In CVVHDF, clearance is a combination of both diffusion and convection. The Cl_{CVVHDF} can be mathematically approximated, providing the blood flow rate is greater than 100 mL/min and the dialysate flow rate (DFR) is between 8 and 33 mL/min, as

$$Cl_{CVVHDF} = (UFR \times f_u) + Cl_{diffusion}$$

where $Cl_{diffusion}$ is the clearance via diffusion from plasma water to the dialysate. In the clinical setting, it is not possible to separate these two components (UFR and DFR) of Cl_{CVVHDF}. In essence the Cl_{CVVHDF} is calculated as the product of the combined ultrafiltrate and dialysate volume (V_{df}) and the concentration of the drug in this fluid (C_{df}) divided by the plasma concentration (C_p^{mid}) at the midpoint of the V_{df} collection period.

⑩ Individualization of therapy for a patient receiving CRRT is dependent on the patient's residual renal function and the clearance of the drug by the mode of CRRT the patient is receiving. There are differences in the rate of drug removal, not only between the three primary modes of CRRT, but also within each mode.[135,140–143] This is a result of differences in the filter membrane composition, variable degrees of drug binding to the membrane, and permeability characteristics of the membrane.[143–147] The primary factors that influence drug clearance during CRRT are thus the ultrafiltration rate, blood flow rate, and dialysate flow rate. For example, clearance in CVVH is directly proportional to the ultrafiltration rate, whereas clearance during CVVHDF, which depends on both the ultrafiltration rate and the dialysate flow rate, increases as either flow rate increases. An increase in the ultrafiltration flow rate (5–45 mL/min) and dialysate flow rate (8.3–33.3 mL/min), however, can have dramatic effects on the clearance of agents such as ceftazidime during CVVH and CVVHD, respectively (Fig. 51–5).[147] Another factor that changes drug dosing is the type of RRT used in the patient. CRRT can rapidly remove excess fluid from edematous patients, thereby changing the volume of distribution (V_D) of drugs with limited distribution (low V_D suggesting a greater proportion in the plasma or extracellular fluid) fairly rapidly. Drug clearances attained by IHD, CRRTs, and hybrid RRTs all differ from each other and must be added to any endogenous drug clearance that the patient generates.[135] An algorithmic approach for drug dosage adjustment in patients undergoing CRRT has been proposed.[141] In CRRT, the clearance of a given agent may be ascertained from published reports.[141,148,149] Table 51–10 summarizes the sieving coefficients of frequently used drugs. These data can be used to design initial dosage regimens for patients receiving CVVH.[140,143]

For example, IM is a 48-year-old, 60 kg man with an S_{cr} that has increased from 2.3 mg/dL to 7.2 mg/dL (203–636 μmol/L) over 3 days. The residual Cl_{cr} value in this patient, calculated using the Jeliffe equation (see Chapter 49), is 4.8 mL/min (0.080 mL/s). The consulting nephrologist recommends that CVVHDF be initiated

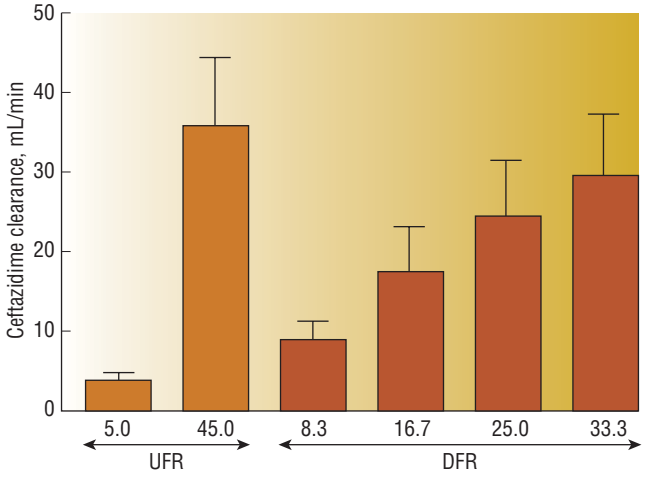

FIGURE 51-5. The effect of increasing ultrafiltration rate (UFR in milliliters per minute) and dialysate flow rate (DFR in milliliters per minute) on the clearance of ceftazidime. *(Adapted from reference 147.)*

TABLE 51-10 Predicted and Measured Sieving Coefficients of Selected Drugs[103,140–143,148,149]

Drug	Predicted	Measured
Amikacin	0.95	0.88
Amphotericin	0.01	0.32–0.4
Ampicillin	0.80	0.6–0.69
Cefepime	0.97	0.47–0.97
Cefoperazone	0.10	0.27–0.69
Cefotaxime	0.62	0.55–1.1
Cefoxitin	0.30	0.32
Ceftazidime	0.90	0.38–0.78
Ceftriaxone	0.10	0.71–0.82
Clindamycin	0.25	0.49–0.98
Digoxin	0.75	0.96
Erythromycin	0.25	0.37
5-fluorocytosine	0.96	0.98
Gentamicin	0.95	0.81–0.75
Imipenem	0.80	0.78
Metronidazole	0.80	0.80
Mezlocillin	0.68	0.68
N-acetylprocainamide	0.80	0.92
Nafcillin	0.20	0.47
Netilmicin	–	0.85
Oxacillin	0.05	0.02
Phenobarbital	0.60	0.86
Phenytoin	0.10	0.45
Procainamide	0.80	0.86
Theophylline	0.47	0.85
Tobramycin	0.95	0.78–0.86
Vancomycin	0.90	0.5–0.8

using a Fresenius F-80 filter at blood, ultrafiltrate, and dialysate flow rates of 150, 15, and 33.3 mL/min, respectively. The patient is to receive cefepime while on CVVHDF. The patient's residual cefepime clearance (Cl_{RES}) can be estimated using the following regression equation relating Cl_{cr} and cefepime clearance:

$$Cl_{RES}\,(mL/min) = [0.96 \times (Cl_{cr})] + 10.9$$
$$Cl_{RES} = [0.96 \times (4.8)] + 10.9$$
$$= 15.5\ mL/min\ (equivalent\ to\ 0.26\ mL/s)$$

The total clearance while on CVVHDF would be the sum of the patient's residual clearance and the cefepime clearance associated with CVVHDF (which can be approximated as described above) as follows:

$$Cl_{CVVHDF} = [(UFR + DFR) \times f_u)]$$
$$Cl_{CVVHDF} = [(15 + 33) \times 0.97]$$
$$Cl_{CVVHDF} = 47\ mL/min$$
$$Cl_T = CL_{RES} + CL_{CVVHDF}$$
$$Cl_T = 15.5\ mL/min + 47\ mL/min = 62.5\ mL/min$$
$$(equivalent\ to\ 1.04\ mL/s)$$

This patient's clearance value can be used to adjust the cefepime dose as described below. The cefepime clearance in a patient with normal renal function would be calculated as:

$$Cl_{norm}(mL/min) = [0.96 \times (Cl_{cr})] + 10.9$$
$$Cl_{norm} = [0.96 \times 120] + 10.9$$
$$Cl_{norm} = 126.1\ (eqivalent\ to\ 2.11\ mL/s)$$

The dosage adjustment factor would then be

$$Q = Cl_T/Cl_{norm}$$
$$Q = 62.5 \div 126 = 0.49$$

For this patient's situation, the normal regimen of cefepime would be 2,000 mg (D_n) every 12 hours (τ_n). If one wanted to maintain D_n and extend the dosing interval (τ_n), then τ_f would be calculated as:

$$\tau_f = \tau_n/Q$$
$$\tau_f = 12\ hours/0.49$$
$$\tau_f \approx 24\ hours$$

This approach suggests the patient should receive cefepime 2,000 mg every 24 hours. If the additional clearance associated with CVVHDF (40.2 mL/min [0.67 mL/s]) was not considered, the calculated dosing interval would have been considerably longer. Several variables can affect the outcome of these calculations, including the multiple variables within the dialysis therapy—for example, UFR, blood flow rate, and DFR—and interpatient variability in nonrenal and renal drug clearance, to name just two.

Intermittent Hemodialysis Limitations of IHD-based dosing charts include variability in the patient's individual pharmacokinetic parameters, differences in the dialysis prescription, such as dialyzer blood flow or duration, and the use of new IHD dialyzers. The approach to hemodialysis may also change on a daily basis, especially in unstable individuals with ARF. This could include, for example, the dialyzer/filter used, the duration, the degree of hemofiltration compared with convection, and the blood flow rate. Individualization of a dosing regimen may require daily assessment of the clinical status of the patient and any planned or recently administered hemodialysis.

Overall, there are numerous potential pharmacokinetic and pharmacodynamic alterations to be aware of in the patient with AKI. Unfortunately, there is a dearth of data to quantify these changes, and even less evidence to prove that if one incorporates these considerations into patient care, the associated outcomes will be improved.

EVALUATION OF THERAPEUTIC OUTCOMES

Vigilant monitoring of patients with AKI is essential, particularly in those who are critically ill (Table 51–11). Once the laboratory-based tests (e.g., urinalysis and fractional excretion of sodium

TABLE 51-11 Key Monitoring Parameters for Patients with Established Acute Kidney Injury

Parameter	Frequency
Fluid ins/outs	Every shift
Patient weight	Daily
Hemodynamics (blood pressure, heart rate, mean arterial pressure, etc.)	Every shift
Blood chemistries	
Sodium, potassium, chloride, bicarbonate, calcium, phosphate, magnesium	Daily
Blood urea nitrogen/serum creatinine	Daily
Drugs and their dosing regimens	Daily
Nutritional regimen	Daily
Blood glucose	Daily (minimum)
Serum concentration data for drugs	After regimen changes and after renal replacement therapy has been instituted
Times of administered doses	Daily
Doses relative to administration of renal replacement therapy	Daily
Urinalysis	
Calculate measured creatinine clearance	Every time measured urine collection performed
Calculate fractional excretion of sodium	Every time measured urine collection performed
Plans for renal replacement	Daily

calculations) have been conducted to diagnose the cause of AKI, they usually do not have to be repeated. In established AKI, daily measurements of urine output, fluid intake, and weight should be performed. Vital signs should be monitored at least daily, more often if patient acuity of illness is high. Daily blood tests for electrolytes, BUN, and a complete blood cell count should be considered routine for hospitalized patients.

Therapeutic drug monitoring should be performed for drugs that have a narrow therapeutic window that can be measured by the hospital laboratory. If results from these serum drug concentrations cannot be obtained in a timely fashion (<24 hours), then their value is limited. When considering approaches to measuring serum concentrations, consensus is limited. Measuring a serum drug concentration prior to hemodialysis has the advantage of allowing time for the result to be reported and redosing done shortly after dialysis with minimal delay. This is especially important if the desired pharmacologic effects are lost during or after hemodialysis is complete because the serum concentrations have become subtherapeutic. Knowledge based on previous observations of how a particular agent is removed for a given dialysis approach and any prehemodialysis serum concentration of the agent can assist in estimating the amount removed and predicting any necessary postdialysis dose. Serum concentrations drawn after hemodialysis may reflect plasma concentrations that are transiently depressed until the drug can reequilibrate from the tissues (plasma rebound effect). The advantage with an after-dialysis level is the greater accuracy in determining how much drug was cleared during hemodialysis, but this may delay reestablishing target effects. Greater therapeutic drug monitoring may be necessary in patients with AKI than what is done routinely for other patients because of the potential changes in dynamic status (changing volume status, changing renal function, and RRTs) of patients with AKI.

PHARMACOECONOMIC CONSIDERATIONS

AKI is a large financial burden on the healthcare system. Much of this cost is incurred because of extended ICU stays which are inherently expensive. Healthcare costs may also vary by the modality of dialysis a patient is receiving. A post-hoc analysis of a multicenter, multinational study conducted in 2000-01 estimated that the total cost difference between continuous and intermittent RRT in critically ill patients ranges from $3630/day more with continuous RRT to $379/day more with intermittent RRT.[155] In addition, it is estimated that an S_{cr} increase ≥0.5mg/dL (≥44 μmol/L) is associated with a 6.5-fold increase in odds for mortality, 3.5-day increase in length of stay, and $7,500 (1998 dollars) in excess hospital costs, and average hospital costs in patients requiring RRT are around $50,000.[150,151] Higher costs have been associated with the severity of AKI using the RIFLE criteria.[152] Most patients who survive AKI regain life-sustaining renal function, but the 5% who do not regain renal function[23] continue to incur the economic and personal costs of dialysis or kidney transplantation. The financial burden is estimated to be over $50,000 per year greater than the non-dialysis-dependent patient whose kidneys recovered from AKI. Nonetheless, patients who required RRT for their AKI generally have a good quality of life after recovery.[151]

Medical intervention costs can be normalized to assess total costs using quality-adjusted life-years (QALYs) gained by the intervention. The use of a QALY approach to treatment of critically ill patients with AKI indicates that treating these patients is very expensive relative to other common medical interventions.[153] For example, in 2001, the treatment of critically ill AKI patient cost per QALY was $168,711, compared with treatment of acute myocardial infarction cost per QALY of $45,000, and the routine treatment of hypertension cost per QALY of $31,321.[154] A typical cost per QALY of <$100,000 is considered cost-effective. Another study found that daily hemodialysis was cost effective when compared to alternate-day hemodialysis with about $5000 per QALY gained.[156] Overall, more research needs to be done to improve the AKI survival rate to reduce this cost per QALY. Furthermore, it underscores the need to prevent the occurrence of AKI in the first place.

CONCLUSION

The unique characteristics of AKI compared with CKD can lead to notable differences in how renal function is measured and how treatment regimens are developed. Most management approaches currently involve prevention and support of the patient once AKI is established, so as to minimize the potential for additional harm to either the patient or the kidney. Monitoring approaches and pharmacologic regimens should consider frequent changes in the clinical presentations, with most decisions considered short term. Understanding the constantly changing status inherent to AKI and how to adjust management regimens is a key component to optimizing therapy.

ACKNOWLEDGMENT

We gratefully acknowledge Ann Spencer, PharmD, and Bruce Mueller, PharmD, for their contributions to the prior editions of this chapter.

ABBREVIATIONS

ACE: Angiotensin-converting enzyme
AIN: Acute interstitial nephritis
AKI: Acute kidney injury
AKIN: Acute Kidney Injury Network
ANP: Atrial natriuretic peptide
ARB: Angiotensin receptor blocker
ARF: Acute renal failure
ATN: Acute tubular necrosis
BTP: Beta trace protein
BUN: Blood urea nitrogen
CIN: Contrast-induced nephropathy
CKD: Chronic kidney disease
CL_{cr}: Creatinine clearance
CRRT: Continuous renal replacement therapy
CT: Computed tomography
CVVH: Continuous venovenous hemofiltration
CVVHD: Continuous venovenous hemodialysis
CVVHDF: Continuous venovenous hemodiafiltration
EPO: Erythropoietin alpha
ESKD: End-stage kidney disease
FE_{Na}: Fractional excretion of sodium
GFR: Glomerular filtration rate
ICU: Intensive care unit
IHD: Intermittent hemodialysis

IL-18: Interleukin-18

KIM-1: Kidney injury molecule 1

KUB: Kidney ureter bladder

L-FABP: Liver-type fatty acid binding protein

NAC: *N*-acetylcysteine

NGAL: Neutrophil gelatinase-associated lipocalin

NSAID: Nonsteroidal antiinflammatory drug

QALY: Quality-adjusted life-year

RIFLE: Risk, Injury, Failure, Loss of Kidney Function, and End-Stage Kidney Disease

RRT: Renal replacement therapy

S_{cr}: Serum creatinine

CHAPTER 52

Chronic Kidney Disease: Progression-Modifying Therapies

VIMAL K. DEREBAIL, ABHIJIT V. KSHIRSAGAR, AND MELANIE S. JOY

KEY CONCEPTS

1. The prevalence of chronic kidney disease (CKD) is estimated at nearly 25 million people in the United States.
2. Because the development of CKD is a complex phenomenon, the Kidney Disease Outcomes Quality Initiative (K/DOQI) has recommended categorizing risk factors associated with CKD as susceptibility, initiation, and progression factors.
3. Reduction of kidney mass, development of glomerular hypertension, and intratubular proteinuria are key mechanisms responsible for the progression of CKD.
4. CKD is classified into five stages based on the presence of kidney structural damage (e.g., proteinuria) and/or kidney function (glomerular filtration rate). Stage 1 is indicative of mild structural changes with "normal" kidney function, while stage 5 is analogous to end-stage renal disease when patients are approaching the need for dialysis or kidney transplantation.
5. Serum creatinine concentration is not a reliable marker of kidney function among the elderly, the malnourished, and children. Therefore, it is important to estimate the glomerular filtration rate rather than just measuring the serum creatinine, especially in these three populations.
6. Stage 5 CKD manifests as asterixis, pruritus, dysgeusia, nausea, vomiting, anorexia, weight loss, and susceptibility to bleeding. These signs and symptoms of uremia drive the decision to implement kidney replacement therapy.
7. The progression of CKD can be slowed by optimizing blood pressure control and among diabetics blood glucose control.
8. Diabetic patients with or without hypertension who demonstrate persistent microalbuminuria despite intensive insulin therapy should have their angiotensin-converting enzyme inhibitor (ACEI) or angiotensin receptor blocker (ARB) dose titrated to achieve maximal suppression of urinary albumin excretion to halt or slow CKD progression.
9. ACEIs and ARBs are key pharmacologic treatments of chronic kidney disease because of their hemodynamic and blood pressure reduction effects, which help to limit kidney disease progression.
10. Dietary protein restriction, lipid-lowering interventions, cessation of smoking, and symptom control of anemia have been suggested to slow the rate of progression of CKD; however, the utility of these interventions remains unclear.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

Under normal conditions each of the 2 million nephrons of the kidneys work in an organized fashion to filter, reabsorb, and excrete various solutes and water. The kidney is the primary regulator of sodium and water balance, as well as of acid-base homeostasis. The kidney also produces hormones necessary for red blood cell synthesis and calcium homeostasis. Dysregulation of kidney function is classified as acute kidney disease and chronic kidney disease. Acute kidney failure refers to the rapid loss of kidney function over days to weeks. Chronic kidney disease (CKD), also called *chronic renal insufficiency* or *progressive kidney disease* by some, is defined as a progressive loss of function occurring over several months to years and is characterized by the gradual replacement of normal kidney architecture with parenchymal fibrosis.

The working group of the National Kidney Foundation's (NKF) Kidney Dialysis Outcomes and Quality Initiative (K/DOQI) has developed a CKD classification system based on the presence of structural kidney damage and/or functional changes in glomerular filtration rate (GFR) present for a period of 3 months or more.[1] CKD is categorized by the level of kidney function (as defined by GFR) into stages 1 through 5, with each increasing number indicating a more advanced stage of the disease (Table 52–1).[1] The use of GFR versus serum creatinine concentration (henceforth, serum creatinine) to define the stages of CKD was chosen because the serum creatinine alone is an inaccurate index of kidney function and there is marked variability in GFR among subjects with similar serum creatinine values (see Chap. 50). Although the stages are defined functionally by the GFR, the classification system also accounts for

TABLE 52-1 Definition and Prevalence of the Stages of Chronic Kidney Disease[2,3]

Stage	Glomerular Filtration Rate[a]	Prevalence[c]
1	≥90[b]	3,600,000[d]
2	60–89	6,500,000[d]
3	30–59	15,500,000
4	15–29	700,000
5	<15 (includes only patients on dialysis)[e]	519,100[e]

[a]Glomerular filtration rate in milliliters per minute per 1.73 m^2 (mL/min/m^2) body surface area. To convert to mL/s/m^2 multiply values by 0.00963.
[b]Chronic kidney disease can be present with a normal or near normal GFR if other markers of kidney disease are present, such as proteinuria, hematuria, biopsy results showing kidney damage, or anatomic abnormalities (e.g., cysts).
[c]Applied to 2000 U.S. Census.

[e]ESRD prevalent patients from USRDS data through 2007 (USRDS 2009 Annual Data Report).

structural evidence of kidney damage. Normal kidney function in adults is approximately 120 mL/min/1.73 m^2 (1.16 mL/s/m^2) based on measured GFR. Even though a GFR of >90 mL/ min/1.73 m^2 (>0.87 mL/s/m^2) is considered normal kidney function, a patient can be diagnosed with stage 1 CKD if the patient has proteinuria, hematuria, or evidence via a kidney biopsy of structural damage. Stage 5 CKD was previously referred to as end-stage renal disease (ESRD) or end-stage kidney disease. As a note to the clinician, a Medicare ICD-9 code exists for stage 6 CKD and is primarily for the purposes of billing for services. This designation represents patients with ESRD [eGFR<15mL/min/1.73m^2 (<0.14 mL/s/m^2)] receiving renal replacement therapy. In this chapter, stage 5 CKD will refer to patients with eGFR<15mL/min/1.73m^2 (<0.14 mL/s/m^2) or patients receiving replacement therapy in order to maintain consistency with the CKD literature.

EPIDEMIOLOGY OF CKD

1 The epidemiology of stage 5 CKD, or ESRD, has been well documented through the efforts of the USRDS, a national data system that collects, analyzes, and distributes information about U.S. patients on hemodialysis and peritoneal dialysis, as well as kidney transplant recipients.[2] Beginning in 2008, the USRDS Report has also included data regarding the earlier stages of CKD, drawing from both National Health and Nutrition Examination Survey (NHANES) data and claims data. In NHANES III and subsequent populations, the prevalence of CKD at any stage using present definitions is estimated between 13% and 16%, representing over 25 million individuals.[2,3] Stage 3 CKD [eGFR <60mL/min/1.73 m^2] has risen from 5.7% in NHANES III (1988–1994) to 8.1% in the more recent NHANES population (2003–2006).[4] Claims data for 2006 suggest that CKD prevalence among those 65 years or older is 6.4% using traditional claims codes and 4.2% using the more recent coding system.[4] Although less than that in NHANES, the data represent a significant increase in CKD prevalence likely due in part to increases in awareness and reporting. The CKD prevalence is similar to that of other chronic conditions such as hypertension, diabetes mellitus, and cardiovascular disease.

In the United States alone, there are several major epidemiologic studies in progress to better describe the natural history of CKD, its progression, and concurrent morbidities. One study targets individuals with polycystic kidney disease,[5] while another study targets African Americans with hypertensive nephrosclerosis.[6] The Chronic Renal Insufficiency Cohort (CRIC) study, funded by the National Institutes of Health[7] and the Fresenius and Amgen, Inc. cosponsored study (Stride Registry)[8] are investigating progressive CKD and its relationship with comorbid cardiovascular disease. The NKF has recognized the importance of early detection and initiated the Kidney Early Evaluation Program (KEEP)[9] to provide free screening and education for people at high risk of developing kidney disease. Baseline characteristics have largely confirmed the previously reported demographic and clinical factors associated with CKD.[10,11] Perhaps some of the most alarming data from KEEP was the low awareness of the disease. Less than 10% of patients were aware of this diagnosis, and even among those with later stages of CKD (stages 3 to 5) only 11% of patients were aware of the diagnosis.[11]

USRDS estimates of new cases of stage 5 CKD necessitating renal replacement therapy increased by 5% to 10% per year during the two decades spanning 1980 to 2000.[2] However, since 2002, the rate of increase had declined to less than 1% to 2% per year.[2] A potential factor attributed to this decline has been the implementation of angiotensin-converting enzyme inhibitor (ACEI) and angiotensin receptor blocker (ARB) therapy as a standard of care for those with early stage CKD.[12] At present, the four most common causes of incident stage 5 CKD in the United States are diabetes mellitus (158 cases per million), hypertension (101 cases per million), glomerulonephritis (25 cases per million), and polycystic kidney disease (9 cases per million).[2]

TABLE 52-2 Risk Factors Associated with Chronic Kidney Disease

Risk Factor
Susceptibility
Advanced age
Reduced kidney mass and low birth weight
Racial/ethnic minority
Family history
Low income or education
Systemic inflammation
Dyslipidemia
Initiation
Diabetes mellitus
Hypertension
Glomerulonephritis
Progression
Hyperglycemia (among diabetic patients)
Hypertension
Proteinuria
Obesity
Smoking

2 It is often assumed that all patients with stage 1 or 2 CKD progress continuously toward stage 5. Thus, information on risk factors obtained from USRDS data is assumed to be generalizable to all stages of CKD. Early data from the KEEP and CRIC studies offer some support for this assumption.[10,11] However, further complicating these issues is the fact that the development and progression of the early stages of CKD is a complex phenomenon.[13] The risk factors associated with CKD are numerous and varied and many of these are not those one would traditionally consider as having a direct influence on the causal pathway. The working group of K/DOQI has recommended categorizing CKD risk factors as susceptibility factors, initiation factors, or progression factors to help clinicians stratify the overall risks of individual patients (Table 52–2).[14]

In this chapter the initiation and progression factors associated with the development of CKD are reviewed. Because diabetes mellitus and hypertension are the two most prevalent etiologies for CKD, the course and treatments that have been proven to slow the progressive kidney function decline are critically evaluated. This chapter focuses on the early CKD stages, that is, stages 1, 2, and 3, which are the critical battleground if one hopes to minimize the number of patients who ultimately require renal replacement therapy. CKD is a continuous and progressive disease state that often results in the appearance of several concomitant complications that commence at various stages in the progression of the disease. The pathophysiology, consequences, and complications of CKD that tend to become evident in those with stage 4 or 5 CKD are discussed in Chap. 53 along with treatment options and monitoring parameters.

ETIOLOGY

SUSCEPTIBILITY FACTORS

CKD susceptibility factors include advanced age,[15] low income or education,[16,17] and racial/ethnic minority status,[18] as well as reduced kidney mass,[19] low birth weight,[19,20] and family history of CKD.[21] These factors have not been proven to directly cause kidney damage. Novel proposed susceptibility factors are systemic inflammation[22,23] and dyslipidemia.[24,25] Although, most of these susceptibility factors

are not amenable to pharmacologic or lifestyle interventions, they are useful for identifying populations that are at high risk of CKD.

INITIATION FACTORS

❸ Initiation factors are conditions that directly result in kidney damage and are modifiable by pharmacologic therapy. Diabetes mellitus, hypertension, autoimmune diseases, polycystic kidney disease, systemic infections, urinary tract infections, urinary stones, lower urinary tract obstruction, and nephrotoxicity are all considered initiation factors. Because diabetes mellitus, hypertension, and glomerular diseases are, respectively, the three most common causes of CKD in the United States, the following discussion focuses on these conditions.

Diabetes Mellitus

Approximately 20% to 40% of those with diabetes mellitus will develop diabetic CKD.[26] Given the greater prevalence of type 2 diabetes mellitus, the majority of patients who develop diabetes-associated CKD are those with type 2 disease. Although not all individuals with diabetic nephropathy progress to stage 5 CKD, the lifetime risk is considerable. A prospective study of over 300,000 individuals screened from the Multiple Risk Factor Intervention Trial estimated that approximately 3% of individuals with diabetes mellitus will develop stage 5 CKD.[27] Diabetics have a 12-fold greater relative risk of developing stage 5 CKD than those without diabetes. Diabetics also have an increased risk of developing CKD as the result of a "nondiabetic" cause, suggesting an underlying genetic susceptibility to kidney diseases.[28]

Hypertension

Hypertension also increases the risk of CKD, although the exact role as a cause or consequence is often debated as the kidney has a role in the development and modulation of high blood pressure. Hypertension generally develops concomitantly with progressive kidney disease. In the NHANES III survey, a serum creatinine of 1.6 mg/dL (141 μmol/L) or higher for men and 1.4 mg/dL (124 μmol/L) or higher for women was more common in persons with hypertension (9.1%) than in persons without hypertension (1.1%).[29] Recent data suggest that among patients with an estimated GFR of 20 to 70 mL/min/1.73 m^2, over 85% have concomitant hypertension.[30]

Prospective studies have shown that elevated blood pressure increases the risk for the development of CKD among subjects without initial kidney disease. In a study of 316,675 adult managed-care patients with normal baseline kidney function, the likelihood of incident ESRD (stage 5 CKD) was increased in those with elevated baseline blood pressure. The likelihood of CKD development was twofold higher for those with relatively minor elevations in blood pressure, 120 to 129 mm Hg systolic over 80 to 84 mm Hg diastolic as compared with those with blood pressure lower than 120/80 mm Hg. For those with blood pressure greater than 210/120 mm Hg, the likelihood of CKD was fourfold higher.[31]

Data from the Multiple Risk Factor Intervention Trial, a primary prevention trial in coronary heart disease, demonstrated that the overall lifetime risk of developing stage 5 CKD for individuals with hypertension was 5.6%.[32] The risk varied dramatically by level of blood pressure, from 0.33% in those with stage 1 hypertension (systolic blood pressure 140 to 150 mm Hg and/or diastolic blood pressure 90 to 100 mm Hg) to 4.5% for systolic blood pressure levels greater than 180 mm Hg or diastolic blood pressure levels greater than 110 mm Hg over a follow-up period of approximately 16 years.[32]

Glomerulonephritis

Glomerular diseases are also considered initiation factors of CKD. The epidemiology and pathophysiology of glomerular diseases are variable, and thus all diseases should not be lumped into one disease category. Some conditions, such as Goodpasture's disease or Wegener's granulomatosus, may progress rapidly to stage 5 CKD and thus may best be categorized as causes of acute renal failure. Other conditions such as immunoglobulin A (IgA) nephropathy, membranous nephropathy, focal segmental glomerulosclerosis, and lupus nephritis are more indolent and are considered causes of CKD (see Chap. 56). The chronic glomerular diseases progress at variable rates, with loss of GFR ranging from 0.9 to 9.8 mL/min per year.[33–35]

PROGRESSION FACTORS

❹ Progression risk factors are those associated with further declines in renal function. Persistence of the underlying initiation factors (e.g., hypertension, diabetes mellitus, glomerulonephritis, and polycystic kidney disease) themselves may serve as the most important predictors of progressive CKD. Other factors associated with progression include those that may be consequent to the underlying renal disease (hypertension, proteinuria, hyperlipidemia) or independent of the underlying renal disease (smoking, obesity).

Hypertension

The early treatment of hypertension and the achievement of aggressive target values has been demonstrated to slow the rate of progression of CKD.[36] Bakris et al. demonstrated a direct correlation between the level of achieved blood pressure and preservation of kidney function in diabetic patients.[37] Their analysis included 10 studies measuring a change in GFR for diabetic patients treated with various antihypertensive agents. An inverse linear relationship was observed between average attained blood pressure at study completion and average GFR; lower final mean arterial blood pressure resulted in a lower average decline in GFR. Specifically, a systolic blood pressure of 180 mm Hg was associated with a 14 mL/min per year decline in GFR as compared with only a 2 mL/min per year decline in GFR among those with a systolic blood pressure of 135 mm Hg.[37]

An extended follow-up analysis of the MDRD original cohort showed that patients assigned to lower blood pressure target (mean arterial pressure <92 mm Hg) were 32% less likely to develop stage 5 CKD than those in the usual target blood pressure (mean arterial pressure <107 mm Hg).[38] Therefore, low blood pressure slowed the progression of nondiabetic kidney disease even for patients with an existing moderately to severely decreased GFR.

Diabetes Mellitus

Hyperglycemia is an initiation and progression risk factor for CKD. Diabetic nephropathy represents the most common cause for ESRD.[2] In the NHANES population 1999 to 2006, the diagnosis of diabetes is associated with a 2.51 (2.07–3.02, $P<0.001$) odds ratio for CKD, representing the greatest risk factor after older age.[2] The likelihood of developing overt nephropathy varies between type 1 and type 2 diabetes mellitus. Without treatment, nearly 80% of patients with type 1 diabetes and microalbuminuria will develop overt nephropathy and nearly 50% of those with type 1 diabetes, nephropathy and hypertension will develop ESRD within 10 years.[26,39] In contrast, only 20% to 40% of those with type 2 diabetes for over 15 years will demonstrate progressive disease.[26] A recent evaluation of participants in the Diabetes Control and Complications Trial (DCCT) and the Epidemiology of Diabetes Interventions and Complications (EDIC) study suggests the historical estimates of diabetic nephropathy may be inflated, since 17% to 25% of their type 1 diabetic participants developed diabetic nephropathy after 30 years.[40] It is not clear whether the lower incidence represents an improvement in overall care or simply is a by-product of enrollment in these studies. Progression of diabetic nephropathy likely has multiple determinants including

both hypertensive and glycemic control and therefore occurs at a variable rate. As will be discussed, control of both blood pressure and hyperglycemia may attenuate progression of diabetic CKD.

Proteinuria

The importance of proteinuria in the progression of both diabetic and nondiabetic kidney disease has been well documented.[41] In diabetic kidney disease (types 1 and 2), an albumin excretion rate higher than 30 mg per 24 hours (microalbuminuria) strongly predicted the development of overt nephropathy (proteinuria) and subsequent loss of kidney function.[42] In nondiabetic kidney disease, the Modification of Diet in Renal Disease (MDRD) Study-a randomized clinical trial examining oral protein restriction and blood pressure control on progression of preexisting CKD, demonstrated that a patient's baseline level of proteinuria strongly predicted future loss of GFR.[43] Furthermore, individuals with the highest levels of baseline proteinuria benefited most from pharmacologic reduction of blood pressure. Another study of more than 1,800 individuals with varying stages of CKD demonstrated a strong, graded risk of CKD based on the level of proteinuria; a fivefold increased risk of progression was observed for each 1.0 g/day increase in proteinuria.[44]

The joint role of blood pressure and proteinuria in the progression of CKD was investigated by Jafar et al. using data from 11 randomized, controlled trials that compared the efficacy of antihypertensive regimens for patients with predominantly nondiabetic kidney disease.[45] Patients with higher systolic blood pressures and urine protein excretion greater than 1.0 g/day had greater risk for progression of CKD. (P<0.006).[45]

Smoking

Although the adverse effects of smoking on cardiovascular disease are well documented, only recently have the consequences of smoking on the progression of CKD been recognized. Smoking is associated with an acute reduction in GFR and increased heart rate and blood pressure, likely secondary to nicotine exposure.[46] Nicotine has also been associated with an increase in urinary albumin excretion.[46] Significant data exist to suggest that smoking may promote initiation and progression of CKD in subjects with type 1 and type 2 diabetes.[46,47] The "cigarette pack years" was an independent predictive factor for CKD progression among diabetic subjects.[48] In addition, smoking has also been associated with the diagnosis of CKD in those with hypertension, especially among black subjects.[49] Some studies have demonstrated an association between smoking and albuminuria[50] and the development of stage 5 CKD.[51] Baseline data from the aforementioned CRIC study also demonstrate a modest association between smoking and CKD.[10] Smoking has also been identified as a risk factor for progression in patients with IgA nephropathy, polycystic kidney disease, and systemic lupus erythematosus.[46,52]

Hyperlipidemia

Dyslipidemia may be associated with kidney disease. CKD with or without nephrotic syndrome is frequently accompanied by abnormalities in lipoprotein metabolism. The prevalence of hyperlipidemia appears to increase as kidney function declines, and hyperlipidemia is a characteristic of the nephrotic syndrome.[53] Elevated plasma total and low-density lipoprotein cholesterol occurs in 85% to 90% of patients with decreased kidney function and proteinuria greater than 3 g/day. Approximately 50% of these patients have low levels [<35 mg/dL (<0.91 mmol/L)] of high-density lipoprotein cholesterol, and 60% have triglyceride concentrations greater than 200 mg/dL (2.26 mmol/L).[53] Three epidemiologic studies[24,25,54] demonstrated that dyslipidemia predicts incident CKD among individuals considered at low risk for CKD.[55]

Obesity

Several studies have evaluated the association between obesity and development of CKD.[56,57] Iseki et al. examined the relationship between body mass index (BMI) and the development of ESRD from a large population of Japanese subjects participating in a community-based screening.[57] BMI was associated with an increased risk of the development of ESRD in men but not in women. Population data from Kaiser Permanente revealed an increased risk of ESRD in overweight and obese subjects.[56] The risk of ESRD was directly related to the magnitude of obesity and remained even after adjustment for diabetes and hypertension.[56] Another study showed that a BMI ≥25 kg/m^2 at age 20 years is associated with a threefold increase in risk of CKD compared with a BMI lower than 25 kg/m^2. Obesity (BMI ≥30 kg/m^2) among men and morbid obesity (BMI ≥35 kg/m^2) among women were associated with three- to fourfold increases in risk.[58]

More recent studies have provided some conflicting data. The Framingham Offspring Study demonstrated an increased risk for CKD among the obese (BMI ≥30 kg/m^2) but not among the overweight (BMI ≥25 kg/m^2 to <30 kg/m^2).[59] However, this association was not apparent after adjustment for traditional cardiovascular risk factors of diabetes, hypertension, and dyslipidemia. A study of Korean men without diabetes or hypertension demonstrated a fourfold increase in the risk for CKD among those gaining >0.75kg/year, even with normal weight at baseline.[60] Other studies have demonstrated elevated inflammatory markers associated with CKD in those with higher BMI.[61,62] Finally a meta-analysis of 16 cohort studies of body weight and kidney disease demonstrated a higher risk among the overweight and obese, particularly in women.[63] These conflicting data highlight a need for further study to this potential relationship between body weight and kidney disease risk.

OTHER FACTORS

Other potential risk factors associated with CKD include hyperuricemia,[64,65] periodontal disease,[23,66,67] lead exposure,[68] and illicit drug use.[69] Genetic studies have suggested apolipoprotein E variants are associated with progression of CKD in both whites and blacks,[70] and they have identified the nonmuscle myosin heavy-chain type II isoform A (MYH9) gene in association with nondiabetic kidney disease in African Americans.[71,72] The exact role and importance of these factors in initiating or sustaining renal damages are not yet clear and require additional study.

PATHOPHYSIOLOGY

As evidenced by the variety of initiation and progression factors, kidney damage can result from heterogeneous causes. Diabetic nephropathy is characterized by glomerular mesangial expansion; in hypertensive nephrosclerosis, the kidney's arterioles have arteriolar hyalinosis; and renal cysts develop in polycystic kidney disease. Therefore, the initial structural damage may depend on the primary disease affecting the kidney. However, the majority of progressive nephropathies share a final common pathway to irreversible renal parenchymal damage and ESRD (Fig. 52–1).[73] The key elements of this pathway are (1) loss of nephron mass, (2) glomerular capillary hypertension, and (3) proteinuria.

The exposure to any of the initiation risk factors can result in loss of nephron mass. The remaining nephrons hypertrophy to compensate for the loss of renal function and nephron mass.[73] Initially, this compensatory hypertrophy may be adaptive. Over time, the hypertrophy can lead to the development of intraglomerular hypertension, possibly mediated by angiotensin II.[74]

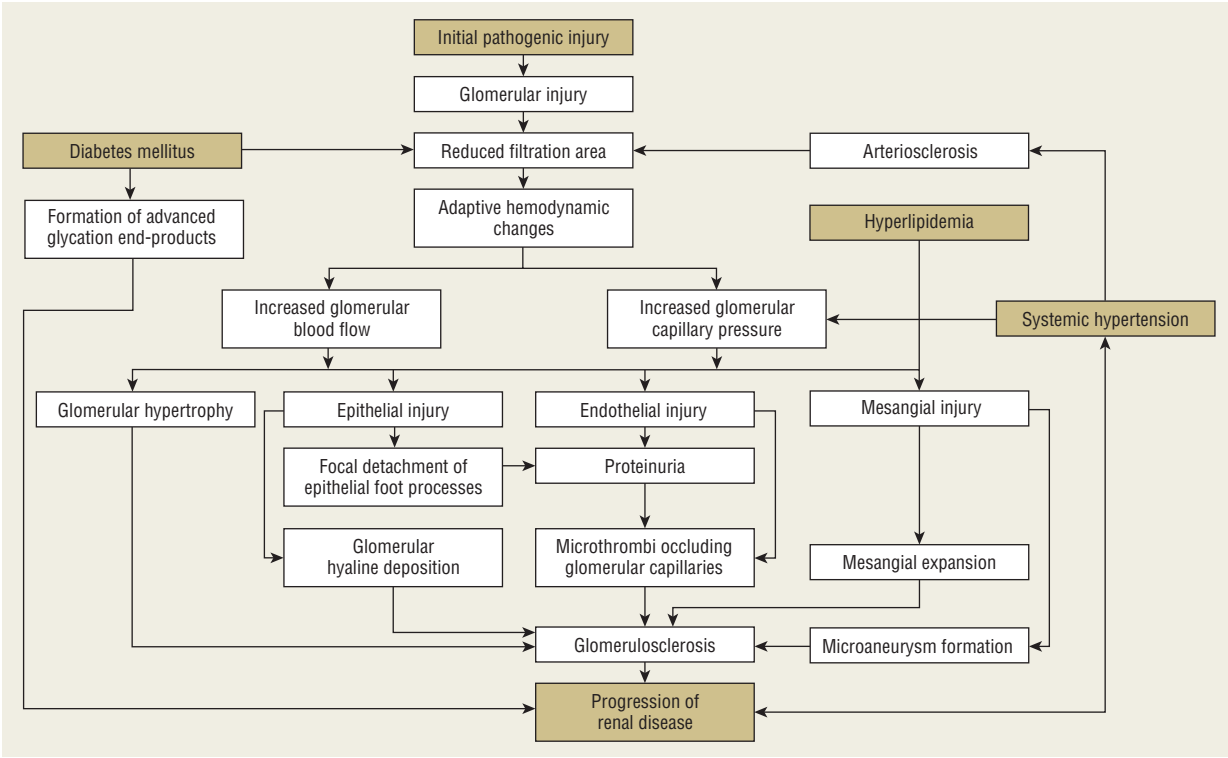

FIGURE 52-1. Proposed mechanisms for progression of renal disease.

Angiotensin II is a potent vasoconstrictor of both afferent and efferent arterioles, but it preferentially affects the efferent arterioles, leading to increased pressure within the glomerular capillaries and consequent increased filtration fraction. The development of intraglomerular hypertension usually correlates with the development of systemic arterial hypertension. High intraglomerular capillary pressure impairs the size-selective function of the glomerular permeability barrier, resulting in increased urinary excretion of albumin and frank proteinuria.[74] Angiotensin II may also mediate renal disease progression through nonhemodynamic effects.[75]

Proteinuria alone may promote progressive loss of nephrons as a result of direct cellular damage[73,75] Filtered proteins such as albumin, transferrin, complement factors, immunoglobulins, cytokines, and angiotensin II are toxic to kidney tubular cells. Numerous studies have demonstrated that the presence of these proteins in the renal tubule activates tubular cells, which leads to the upregulated production of inflammatory and vasoactive cytokines, such as endothelin, monocyte chemoattractant protein (MCP-1), and CCL5 [regulated upon activation, normal T-cell expressed and secreted (RANTES)].[76] Proteinuria is also associated with the activation of complement components on the apical membrane of proximal tubules. Accumulating evidence now suggests that intratubular complement activation may be the key mechanism of damage in the progressive proteinuric nephropathies.[76] These events ultimately lead to scarring of the interstitium, progressive loss of structural nephron units, and reduction in GFR.

CLINICAL PRESENTATION

5 CKD is often asymptomatic, and should be suspected in individuals with conditions such as diabetes, hypertension, genitourinary abnormalities, and autoimmune diseases. In addition, individuals of older age and those with a family history of kidney disease should be considered for CKD screening. Recommended screening studies include serum creatinine and GFR measurement, urinalysis, and/or imaging studies of the kidneys. A novel tool known as SCreening for Occult REnal Disease (SCORED) may also help to identify those with CKD in a cost-effective and noninvasive manner.[77] This self-administered survey predicts that nearly 20% of individuals with all risk factors of diabetes mellitus, advanced age, hypertension, and cardiovascular disease will have an eGFR<60mL/min/1.73m^2.[78] Abnormal elevations of serum creatinine, reflecting decreases in GFR, or presence of urinary or imaging study abnormalities are indications for a full evaluation of CKD.[1] Furthermore, the rate of GFR loss can vary in CKD because of differences in the underlying disease process and extent of kidney damage, treatment responsiveness, and compliance with therapies.

CLINICAL PRESENTATION OF CKD STAGES 1 TO 4

General

- CKD development and progression may be insidious in onset, often without noticeable symptoms. The diagnosis of CKD requires measurement of serum creatinine, estimation of GFR, and assessment of the urine (urinalysis) for protein and/or albumin excretion.
- CKD stages 3, 4, and 5 require further workup to identify the presence of CKD complications of anemia, cardiovascular disease, metabolic bone disease, malnutrition, and disorders of fluids and electrolytes.

Symptoms

- Symptoms are generally absent in CKD stages 1 and 2 and may be minimal during stages 3 and 4. General symptoms associated with stages 1 to 4 include edema, cold intolerance, shortness of breath, palpitations, cramping and muscle pain, depression, anxiety, fatigue, and sexual dysfunction. The classic symptoms associated with stage 5 CKD are discussed in chapters 53 and 54.

TABLE 52-3 Quantification of Proteinuria

Category	24-Hour Collection[a]	Spot Collection: Protein-to-Creatinine Ratio[b]	Spot Collection: Albumin-to-Creatinine Ratio[c]	Timed Collection[d]
Normal	<300 mg/day protein <30 mg/day albumin	<200 mg/g (<22.6 mg/mmol)	<30 mcg/mg (<3.4 mg/mmol)	<20 mcg/min
Microalbuminuria	30–300 mg/day albumin	Not applicable	30–299 mcg/mg (<33.8 mg/mmol)	20–199 mcg/min
Clinical proteinuria or albuminuria	≥300 mg/day protein or albumin	>200 mg/g (>22.6 mg/mmol)	≥300 mcg/mg (<33.9 mg/mmol)	≥200 mcg/min

[a]Milligrams of protein or albumin per 24-hour period.
[b]Milligrams of protein per gram of creatinine (milligrams of protein per millimole of creatinine).
[c]Micrograms of albumin per milligram of creatinine (equal, as a ratio, to milligrams of albumin per gram of creatinine; SI units are milligrams of albumin per millimole of creatinine). The National Kidney Foundation recommendations also cite gender differences for values of spot albumin-to-creatinine ratios that are not included here.
[d]When multiplied by 1,440 minutes in a day, the values obtained are similar to those listed for the 24-hour collection of milligrams per day of albumin, as expected.

Signs

- Cardiovascular-pulmonary: Edema and worsening hypertension, electrocardiographic evidence of left ventricular hypertrophy, arrhythmias, hyperhomocysteinemia, and dyslipidemia
- Gastrointestinal: Gastroesophageal reflux disease, weight loss
- Endocrine: Secondary hyperparathyroidism, decreased vitamin D activation, β_2-microglobulin deposition, and gout
- Hematologic: Anemia of CKD, iron deficiency, and bleeding
- Fluid/electrolytes: Hyper- or hyponatremia, hyperkalemia, and metabolic acidosis

The NKF K/DOQI defines kidney damage in reference to the presence of clinical proteinuria, in addition to the GFR. Clinicians should be aware of the methods available to detect and interpret proteinuria and albuminuria (Table 52–3). In addition, Chap. 50 provides a detailed discussion of the relative merits of the various methods currently available for the detection of urinary protein.

6 Patients with stage 1 or 2 CKD disease usually do not have any symptoms or metabolic derangements such as acidosis, anemia, and bone disease. In addition, the most common measure of impairment of kidney function, serum creatinine, may be only slightly elevated in these early CKD stages. Consequently, estimation of the GFR and assessment for urinary protein is imperative for recognition of early stages of CKD. Because the early stages of CKD are often undetected, the diagnosis requires a high level of suspicion for patients with chronic conditions such as hypertension and diabetes. Signs and symptoms associated with CKD become more prevalent in stages 3 to 5. Anemia, abnormalities of calcium and phosphorus metabolism (secondary hyperparathyroidism), malnutrition, and fluid and electrolyte abnormalities become more common as kidney function deteriorates (see Chap. 53).

ANEMIA

Because the kidneys secrete 90% of the endogenous hormone erythropoietin, a hormone necessary for erythropoiesis, declining kidney function can lead to erythropoietin deficiency and anemia. The prevalence of anemia at specific stages of CKD is difficult to ascertain because of limited available data and use of various definitions.[1] Estimates of anemia [hemoglobin of less than 12 g/dL (120g/L; 7.45 mmol/L)] prevalence for patients with a GFR greater than 80 mL/min per 1.73 m^2 (0.77 mL/s/m^2) range from 1 to 30%.[79] The true prevalence rate estimation is unclear as other factors, such as ethnicity, age, and gender, can also contribute to anemia. Data from the KEEP study targeting a higher risk population, reports anemia [defined as a hemoglobin of <13.5g/dL (<135 g/L; <8.38 mmol/L) in men and <12g/dL ([<120 g/L; <7.45 mmol/L) in women] to occur in 20% of those with stage 1 to 3 CKD, almost 65% of those with stage 4 CKD, and in 75% of those with stage 5 CKD.[80] African Americans were twice more likely to have anemia than whites and Hispanics.[80] Anemia can lead to symptoms of fatigue, weakness, and shortness of breath. However, mild anemia, especially when present for a prolonged time period, can be asymptomatic. The NKF K/DOQI guidelines recommend evaluating hemoglobin levels in all patients with CKD, noting the increase in anemia prevalence beginning with stage 3.[81] The treatment of anemia can improve or resolve symptoms and may help to stabilize kidney function.[82] Chapter 53 discusses the management of anemia in CKD.

CARDIOVASCULAR DISEASE

CKD is associated with a high rate of cardiovascular morbidity and mortality.[83] An epidemiologic study of more than 300,000 individuals demonstrated a strong relationship between GFR and cardiovascular disease: The lower the level of GFR, the higher the incidence of cardiovascular events.[84] In fact, individuals with stages 2 to 4 CKD were more likely to die from cardiovascular disease complications than to survive to the initiation of renal replacement therapy.[85] A recent evaluation of a large database of over 400,000 individuals demonstrated a nearly twofold risk of cardiovascular death among those with CKD.[86] Data from NHANES and KEEP also demonstrate a greater risk of myocardial infarction, stroke, and death among those with CKD.[87] Interestingly, two other recent studies have demonstrated elevated cardiovascular risk among those with a CKD diagnosis based separately on reduced GFR or albuminuria.[88,89] In both studies, those with diminished GFR were considered as a different population than those with only albuminuria, suggesting that reduced GFR and albuminuria may provide separate cardiovascular risk information.[88,89] Consequently, monitoring for the presence or development of cardiovascular disease for patients with CKD is an important aspect of their care. Appropriate traditional and nontraditional cardiovascular risk factor assessments are necessary in the evaluation of the patient with CKD. Guidelines for the evaluation, monitoring, and treatment of cardiovascular diseases for patients with CKD have been published.[83]

DISORDERS OF CALCIUM AND PHOSPHORUS HOMEOSTASIS

Abnormalities in calcium and phosphorus metabolism typically occur in stages 3 to 5 CKD. Secondary hyperparathyroidism, however, can develop earlier despite normal serum calcium and phosphorus levels, at a GFR of 80 mL/min per 1.73 m^2 or below.[90] Thus, to detect secondary hyperparathyroidism and limit the

bone complications, it is recommended that parathyroid hormone concentration, vitamin D levels, and calcium and phosphorus be monitored beginning in stage 3 CKD.[91] Additional systemic benefits of correcting abnormalities in calcium, phosphorus, and parathyroid hormone may include cardiovascular risk reduction. A recent controlled study of 24 CKD patients reported reductions in urinary protein excretion and high-sensitivity C-reactive protein with paricalcitol treatment.[92] Additionally, an uncontrolled study of 10 IgA nephropathy patients reported a 25% reduction in urinary protein after initiation of twice weekly calcitriol therapy to existing angiotensin converting enzymes inhibitors.[93] These studies show preliminary data suggesting the need for more extensive evaluations regarding any protective role of vitamin D on kidney function decline. Chapter 53 discusses the management of bone disease caused by CKD.

MALNUTRITION

Anorexia and malnutrition are complications of CKD. Although there are limited data defining exactly at which stage malnutrition develops, the NKF K/DOQI guidelines recommend evaluating for signs of malnutrition when the GFR is lower than 60 mL/min per 1.73 m^2 (stages 3, 4, and 5).[94] An investigation for malnutrition should include a dietary assessment for protein and calorie intake, serum albumin, and/or assessment of protein appearance in the urine (as a marker of protein intake). Chapter 149 discusses the interpretation of these tests, and Chap. 153 discusses nutritional recommendations for patients with CKD.

TREATMENT

Chronic Kidney Disease

GOAL OF THERAPY

The goal of therapy is to delay the progression of CKD, thereby minimizing the development or severity of associated complications including cardiovascular disease and ultimately limiting the progression to ESRD. Both nonpharmacologic and pharmacologic interventions are available to slow the rate of CKD progression and may also decrease the incidence and prevalence of ESRD.

7 In addition to pharmacologic therapy, the patient with CKD usually will benefit from modest dietary protein. The main purpose of pharmacologic therapy is to control the underlying conditions (such as diabetes mellitus and hypertension) that have incited kidney damage to prevent further loss of kidney function. Patients generally require a multimodality treatment approach irrespective of the cause of their kidney disease. Therapy with ACEIs and/or ARBs is a nearly universal key therapeutic component.

Nonpharmacologic Therapy

Dietary Protein Restriction Experimental studies of kidney disease in animals suggest that dietary protein restriction may delay the rate of progression of kidney function decline.[95] This hypothesis was tested in humans in the MDRD study, a randomized, controlled trial that evaluated the benefits of dietary protein restriction and blood pressure reduction on the rate of CKD progression.[43,96] Most enrolled subjects had nondiabetic kidney disease, and 24% of them had a diagnosis of polycystic kidney disease. Subjects with moderate CKD (GFR of 25 to 55 mL/min per 1.73 m^2) were randomized by dietary protein intake groups (1.3 g/kg per day or 0.58 g/kg per day), in addition to blood pressure grouping, for a total of four groups. Subjects with advanced CKD [GFR 13 to 24 mL/min per 1.73 m^2] were randomized to a low-protein diet (0.58 g/kg/day) or a very-low-protein diet (0.28 g/kg/day) with a ketoamine acid supplement, in addition to blood pressure, also for a total of four groups. After a mean followup of 2.2 years, protein restriction failed to show a statistical benefit in slowing the progression of CKD in any of the study groups. However, a secondary analysis of the MDRD study was conducted and revealed that in those patients with a GFR of less than 25 mL/min per 1.73 m^2 a protein intake of 0.6 g/kg per day was significantly associated with a decreased rate of progressive renal disease.[96] In addition, this analysis showed that the rate of progression to ESRD was significantly reduced by 41% for each 0.2 g/kg per day reduction in dietary protein intake. The discrepancy in results between the primary and secondary analyses can be explained by the different statistical methods used in each of the two analyses, in that the later analysis evaluated participants who were actually compliant with their dietary prescription. The most recent follow-up of the advanced CKD group found no difference in progression to kidney failure but perhaps suggested an increased risk of death in the very-low-protein group. However, data on protein intake at the time of follow-up was not available.[97]

Because of concerns regarding the inadequate statistical power of individual studies, recent meta-analyses have been performed to determine the effect of protein restriction on the progression of CKD.[98–100] The studies have had varying conclusions, although the reduction in loss of GFR was relatively nominal. The most recent randomized trial in diabetic nephropathy[101] was not able to demonstrate renoprotection of a low-protein diet but, most importantly, noted the difficulty that patients had adhering to the requirements of a low-protein diet.

Thus, the available data suggest only a relatively small benefit from dietary protein restriction in CKD patients. Because low-protein diets may lead to malnutrition for patients with advanced CKD and those with nephrotic-range proteinuria, the NKF K/DOQI has advocated a dietary protein intake of 0.6 g/kg per day for patients with a GFR <25 mL/min per 1.73 m^2.[94] Titration of protein intake up to 0.75 g/kg per day is suggested for patients who cannot achieve or maintain adequate nutritional status with the lower protein (0.6 g/kg per day) diet.[94]

Smoking Cessation

Although the effectiveness of smoking cessation on limiting progressive CKD has not been prospectively evaluated, one study suggested that smoking cessation resulted in a protective effect against proteinuria and reduced GFR.[102] This later study showed that although current smokers had a significantly higher albumin excretion (and reduced GFR) versus nonsmokers, those patients who quit smoking had a statistical association with only microalbuminuria.[102] Based on the evolving data concerning the detrimental effects of smoking on the kidney and the well-documented associations with cardiovascular disease, the clinician should educate patients regarding this risk and institute appropriate therapeutic options, both nonpharmacologic and pharmacologic, for smoking cessation. These options are discussed in further detail in Chap. 75.

Pharmacologic Therapy

Guidelines for CKD treatment usually recognize the differences in pathogenesis and course of diabetic and nondiabetic CKD. Consequently, pharmacologic interventions are discussed separately for these conditions within this chapter. The major focus of this chapter is on the impact of ACEI and ARB therapies on progressive CKD. Pharmacologic therapies specific for glomerulonephritis are

discussed in Chap. 56, while therapies for the treatment of complications of kidney disease are covered in Chap. 53.

Diabetic Chronic Kidney Disease

INTENSIVE INSULIN THERAPY

Several large prospective studies performed in the 1990s showed the benefits of blood glucose control in both the development and progression of microvascular complications. The largest of these studies, the DCCT enrolled 1,441 patients with type 1 diabetes mellitus who were randomized to conventional blood glucose control or to intensive glucose control.[103] Conventional control consisted of up to two insulin injections per day guided by blood glucose levels. Intensive control consisted of three or more times daily injections or external insulin pump to a goal hemoglobin A_{1c} ≤6.0% (≤0.06). The main outcome measure of efficacy was retinopathy, a marker of microvascular disease often associated with diabetic nephropathy among individuals with type 1 diabetes mellitus. Roughly half of the patients had mild retinopathy. Intensive insulin control reduced the risk of new occurrences of retinopathy by 76% among those without baseline retinopathy and reduced the risk of progressive retinopathy by 54% among those with baseline retinopathy. Intensive therapy was also associated with a 39% reduction in the development of "microalbuminuria" (urinary albumin excretion ≥40 mg/day) and a 54% reduction in the development of "frank albuminuria" (urinary albumin excretion ≥300 mg/day) compared with conventional therapy. The beneficial effect of intensive therapy on the development of proteinuria persisted even 7 to 8 years after completion of the randomized phase of the DCCT.[104] Individuals initially randomized to the intensive therapy had a 59% reduction in the development of new microalbuminuria, and 84% reduction in the development of albuminuria compared with the conventional group. In the intensive therapy group, follow-up after 30 years of diabetes demonstrated a lower cumulative incidence of diabetic nephropathy (9% vs 25%).[40] However, at least one episode of hypoglycemia occurred in 65% of intensive insulin therapy patients as compared with 35% in the standard treatment group.[104]

The Intensive Glucose Control Study of the United Kingdom Prospective Diabetes Study (UKPDS) also evaluated prevention of microvascular complications among individuals with type 2 diabetes mellitus.[105] Individuals newly diagnosed with type 2 diabetes mellitus were randomized to intensive therapy [goal fasting plasma glucose of <108 mg/dL (<6 mmol/L)] or conventional therapy [goal fasting plasma glucose of <270 mg/dL (<15 mmol/L)] after 3 months of dietary counseling. Individuals in either group could use oral sulfonylureas or insulin. After 10 years of followup, the intensive group had an 11% reduction in median hemoglobin A_{1c} and a 12% reduction in any diabetes-related end point compared with the conventional group. Most of the observed benefit was in a reduction in microvascular end points, primarily proliferative retinopathy.[105]

The DCCT, the UKPDS, and their long-term follow-up provide support for reducing microvascular complications, including nephropathy, with intensive therapy for patients with type 1 and type 2 diabetes mellitus. Intensive therapy can include insulin or oral drugs but employs testing of blood sugar at least three times daily. Furthermore, goals of therapy included an A_{1c} of <7% (<0.07) and preprandial plasma and peak postprandial blood glucose of 92 to 130 mg/dL (5.1 to 7.2 mmol/L) and <180 mg/dL (10.0 mmol/L), respectively.[106] However, recent data suggest that more aggressive glycemic goals [Hgb A_{1c} of <6.0% (<0.06)] may be associated with increased mortality.[107] Clinician's are encouraged to review Chap. 83 for a thorough review of dosing, monitoring, and goals of therapies to treat diabetes mellitus.

OPTIMAL HYPERTENSION CONTROL

The Seventh Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure recommends a goal blood pressure of less than 130/80 mm Hg for patients with CKD.[108] Elevated blood pressure is often more difficult to control for patients with CKD than for those with normal kidney function. Therefore, to achieve adequate blood pressure goals, three or more different blood pressure medications are usually required.[109] Figure 52–2 depicts the proposed algorithm for the management of hypertension for people with CKD and diabetes. The selection of individual classes of drugs for limiting progression of CKD is presented in the following sections.

Reduction of blood pressure in type 1 and type 2 diabetic patients has been associated with lower rates of CKD progression.[37,110–120] The UKPDS,[118] a randomized trial of captopril or atenolol among 1,148 hypertensive type 2 diabetic patients, evaluated the effect of blood pressure reduction to a level of less than 150/85 mm Hg versus less than 180/105 mm Hg on macrovascular and microvascular outcomes. Reductions of 24% in diabetes-related end points, 32% in deaths related to diabetes, 44% in strokes, and 37% in microvascular end points were observed after a median follow-up of 8.4 years.[118] The benefit of blood pressure control has been confirmed in subsequent studies of type 2 diabetic subjects with microalbuminuria.[114,119,121–125] These seminal studies used either ACEI (Table 52–4) or ARB (Table 52–5) classes of drugs, which likely have nonhemodynamic beneficial effects on CKD progression, as discussed below, as well as blood-pressure-lowering effects. In type 1 diabetes with nephropathy, a rigorous blood pressure goal (MAP of ≤92 mm Hg) leads to decreased proteinuria.[126]

Patients diagnosed with both hypertension and diabetes mellitus have been estimated to have up to a sixfold higher risk of developing ESRD than do those patients with diabetes mellitus alone.[109] Adequate blood pressure control can reduce the rate of decline in GFR and the degree of albuminuria for hypertensive type 1 and type 2 diabetic patients.[109] Although all interventions that reduce blood pressure have historically shown reductions in urinary albumin and protein excretion, the ACEIs were the first agents shown to reduce glomerular capillary pressure and volume, which have resulted in preservation of renal function in animal models and human studies.[127,128] Table 52–6 summarizes the documented effects of the other various available antihypertensive agents on renal blood flow and GFR.[129,130]

Antihypertensive Drug Choice 8 Several studies have confirmed the beneficial effects of ACEIs on renal function for patients with and without diabetes and both ACEIs and ARBs remain the mainstay of therapy. Table 52–4 shows the results of the key studies that evaluated more than 100 diabetic subjects followed over 2 to 6 years.[110–112,114–116,131] These studies show that the benefit of ACEI use in CKD is seen in both type 1 and 2 diabetic subjects, across different degrees of kidney damage (normoalbuminuria, microalbuminuria, frank proteinuria, and reduction in GFR), and are drug-class specific. These findings consistently support the role of ACEI therapy in the management of CKD. It is customary to begin at low doses and increase the dose at 4-week intervals to control the level of proteinuria. The dose is usually increased until proteinuria is reduced by 30% to 50% or the development of side effects such as elevations in serum creatinine or potassium occurs.

A meta-analysis that pooled several of the small and large randomized, controlled studies showed beneficial effects of ACEI therapy on diabetic nephropathy.[132] Progression to proteinuria was reduced by 65% for patients with diabetes mellitus and microalbuminuria, and progression of nephropathy (doubling of serum creatinine) was reduced by 40% for patients with overt proteinuria (comprised of 30% diabetics and 70% nondiabetics) (Fig. 52–3).[132] However, a meta-analysis of 127 studies with more than 30,000 subjects suggests

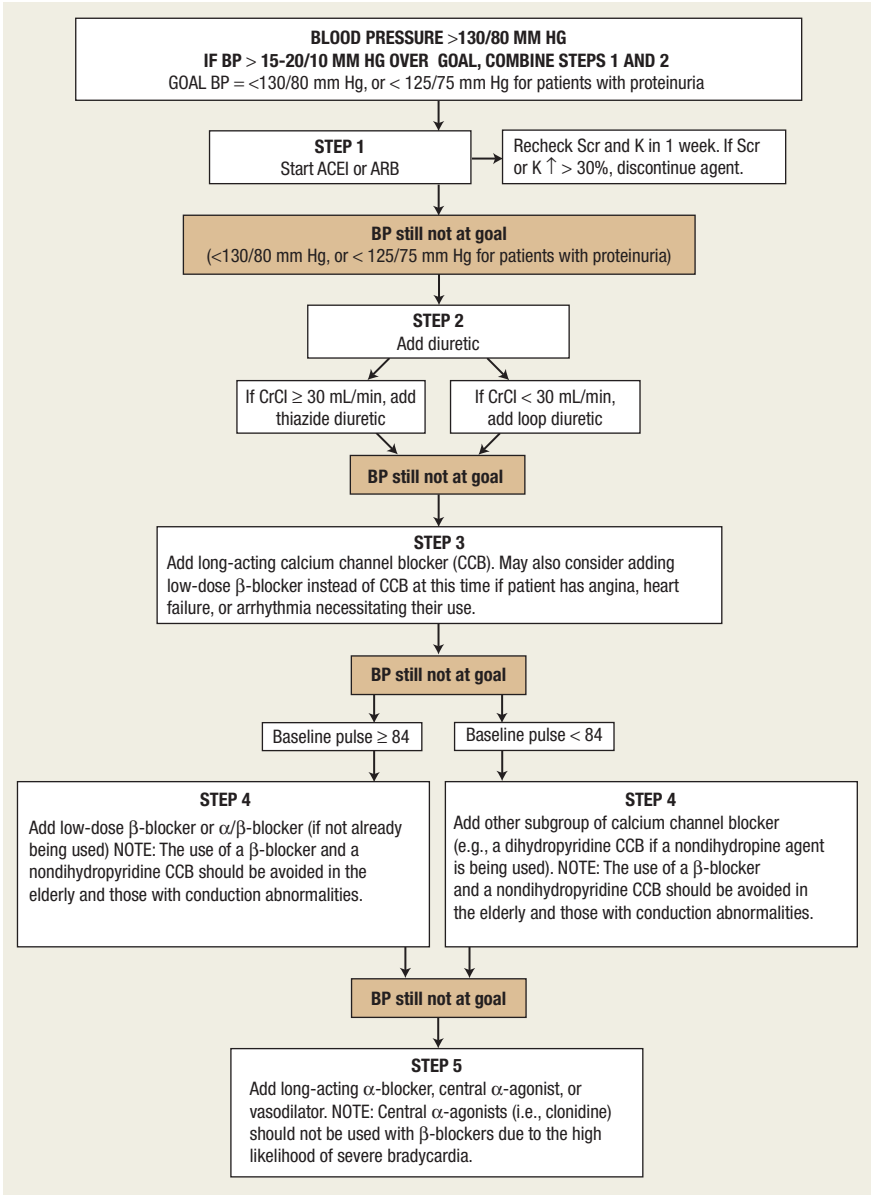

FIGURE 52-2. Hypertension management algorithm for patients with CKD. Dosage adjustments should be made every 2 to 4 weeks as needed. The dose of one agent should be maximized before another is added. (ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; BP, blood pressure; CAD, coronary artery disease; CCB, calcium channel blocker; CHF, congestive heart failure; MI, myocardial infarction; UP:Cr, urinary protein-to-creatinine ratio.) *(Lewis EJ, Hunsicker LG, Bain RP, Rohde RD. The effect of angiotensin-converting-enzyme inhibition on diabetic nephropathy. The Collaborative Study Group. N Engl J Med. 1993 Nov 11;329(20):1456–1462. Copyright © 1993 Massachusetts Medical Society. All rights reserved.)*

that the benefit of ACEIs and ARBs over other pharmacologic agents is related to blood pressure attained during the study rather than to special properties of the ACEI or ARB (e.g., antiproteinuric effects).[133]

The ARBs have also been shown to slow the progression of diabetic kidney disease.[122–125] Table 52–5 summarizes data from several key studies (with at least 100 patients) evaluating ARB efficacy in type 2 diabetes. All patients in these trials had at least a level of proteinuria consistent with microalbuminuria and all were hypertensive. With the exception of one, the studies were of a sufficiently long duration to determine the beneficial effects of ARBs on nephropathy. Of note, the beneficial effect of delaying the onset of diabetic nephropathy was significant in type 2 diabetic patients who received irbesartan 300 mg daily for up to 2 years.[123] A similar trend (although not statistically significant) was observed in those subjects who received a lower dose of irbesartan (150 mg daily). Currently, the data show efficacy of both ACEIs and ARBs in type 2 diabetes, whereas only ACEIs have been adequately evaluated for patients with type 1 diabetes. Although no data exist comparing ACEIs and ARBs in head-to-head trials in type 2 diabetes, in practice these agents are used somewhat interchangeably. ACEIs are typically started as first line with a change to an ARB if not tolerated.

The lack of response among some patients to ACEI or ARB therapy with regards to blood pressure or proteinuria may be due to aldosterone escape in renin-angiotensin-aldosterone system blockade. Type 2 diabetic subjects with nephropathy who had increased aldosterone plasma levels during a mean 35-month treatment with losartan had a faster decline in the rate of GFR compared with those without aldosterone escape.[134] With the thought that further aldosterone blockade may improve outcomes, combination therapy with both ACEIs and ARBs has been investigated in both studies and subsequent metaanalyses.[135–138] In summary, these studies demonstrate a greater reduction in proteinuria with the combination of these agents, with some studies demonstrating a trend to higher serum potassium and serum creatinine concentrations. Unfortunately, none of these are of sufficient duration to determine if the reduction in proteinuria translates to preservation of renal function. It was recently suggested that polymorphisms in the cytochrome P450 (*CYP2C9*) drug metabolizing gene may result in less favorable therapeutic response to the ARB losartan.[139] The Arg144Cys and Ile359Leu polymorphisms are reported to reduce CYP2C9 activity,[140,141] and this may result in formation of metabolites with less pharmacological activity than E-3174.

A recent study has raised concerns with the use of combination ACEI/ARB. The Ongoing Telmisartan Alone and in Combination

TABLE 52-4 Key Angiotensin-Converting Enzyme Inhibitor Studies in Diabetic Patients

Drug, Dose, and Study Design	Baseline Renal Characteristics	Number of Subjects and Disease	Study Duration	Outcome	Reference and Study Name
Captopril 25 mg three times a day; randomized, placebo-controlled trial	UPE ≥500 mg/day, S_{cr} ≤2.5 mg/dL (≤221 μmol/L)	409 type 1 DM	3 years	Risk reduction of doubling S_{cr} was 48% with captopril treatment; subanalysis showed a larger risk reduction with more elevated S_{cr} (76% when the S_{cr} was greater than 2 mg/dL [177 μmol/L])	Lewis et al.[110]
Enalapril once daily; randomized, placebo-controlled trial	Normotensive, UAE 20–200 mcg/min	103 type 2 DM	5 years	Risk reduction of 66.7% for progression to clinical albuminuria with enalapril	Ahmad et al.[111]
Enalapril 10 mg once daily; randomized, placebo-controlled trial	Normotensive, UAE ≤30 mg/day	156 type 2 DM	6 years	Risk reduction of 12.5% for microalbuminuria with enalapril treatment; GFR reductions were two times greater in the placebo-treated patients at 6 years	Ravid et al.[112]
Lisinopril 10 mg once daily with titration to BP; placebo-controlled trial	Normotensive patients with either normoalbuminuria or microalbuminuria	530 type 1 DM	2 years	18.8% lower UPE with lisinopril treatment; greater treatment effect in those with baseline microalbuminuria (34.2 mcg /min vs 1 mcg /min)	EUCLID Study Group[113]
Ramipril 10 mg once daily; randomized, placebo-controlled trial	Normoalbuminuria or microalbuminuria	3,577 type 2 DM	4.5 years	Ramipril lowered risk of overt nephropathy with and without baseline microalbuminuria (relative risk of 0.8); lower UP:Cr at 1 and 4.5 years with ramipril treatment	HOPE and MICROHOPE[114]
Captopril 50 mg twice a day; randomized, placebo-controlled trial	Normotensive patients with microalbuminuria	143 type 1 DM	2 years	Risk reduction of 67.8% for clinical proteinuria with captopril treatment; GFR reductions of 7.9 mL /min per 1.73 m^2 per year in placebo group while stable in captopril group	North American Microalbuminuria Study Group[115]
Enalapril 5 mg once daily, titrated to BP; placebo-controlled trial	Hypertensive, GFR of 30–100 mL/min per 1.73 m^2 (0.29–0.96 mL/s/m^2)	121 type 2 DM	3 years	Clinical albuminuria progression in 7% of enalapril versus 21% of placebo group; enalapril therapy preserved GFR, whereas placebo treatment resulted in a loss of 0.33 mL/min per 1.73 m^2 per month	Lebovitz et al.[116]

BP, blood pressure; DM, diabetes mellitus; GFR, glomerular filtration rate; S_{cr}, serum creatinine; UAE, urinary albumin excretion; UP:Cr, urinary protein-to-creatinine ratio; UPE, urinary protein excretion.

with Ramipril Global Endpoint Trial (ONTARGET) randomized 25,620 patients with established atherosclerotic vascular disease or diabetes with end-organ damage to telmisartan, ramipril, or a combination of the two drugs.[142] The composite outcome of any dialysis, renal transplantation, doubling of serum creatinine, or death occurred more frequently for patients receiving combination treatment than in either of the two other groups, despite a lower degree of albuminuria and less progression to micro- or macroalbuminuria.[142] These findings have led some to advise against the combination of these two agents, however, criticisms of the study have argued that these findings cannot be extrapolated to those with proteinuric renal disease as only 4% of patients in the study had overt proteinuria.[143] Combination therapy with ACEI and ARB likely does have a role for patients with diabetic nephropathy with overt proteinuria and is being evaluated more closely in an ongoing randomized double-blind multicenter clinical trial of Veterans Administration patients (VA NEPHRON D).[144]

TABLE 52-5 Key Angiotensin Receptor Blocker Studies in Diabetic Patients

Drug, Dose, and Study Design	Baseline Characteristics	Number of Subjects and Disease	Duration	Outcomes	Reference and Study Name
Irbesartan 300 mg once daily; amlodipine 10 mg once daily, randomized, placebo-controlled trial	Hypertensive, UPE ≥900 mg/day	1,715 type 2 DM	2.6 years	Irbesartan therapy resulted in a 20% (for placebo) and 23% (for amlodipine) risk reduction in primary composite end point of doubling of S_{cr}, development of ESRD, or death	Lewis et al.[122]
Irbesartan 150 mg once daily; irbesartan 300 mg once daily; randomized, placebo-controlled trial	Hypertensive, AER of 20–200 mcg/min	590 type 2 DM	2 years	Irbesartan 150 mg resulted in a 24% reduction in UAE; irbesartan 300 mg resulted in a 38% reduction in UAE; placebo resulted in a 2% decrease; hazard ratio for diabetic nephropathy was 0.56 and 0.32 in the 150 mg and 300 mg irbesartan groups, respectively	Parving et al.[123]
Losartan 50–100 mg once daily; randomized placebo-controlled trial	Hypertensive, UA:U_{cr} of at least 300 mg/g (33.9 mg/mmol) and S_{cr} 1.3–3 mg/dL (115–265 μmol/L)	1,513 type 2 DM	3.4 years	Losartan therapy resulted in a 16% risk reduction of primary composite end point of doubling of S_{cr}, ESRD, or death; level of proteinuria declined by 35% with losartan therapy	Brenner et al.[124]
Irbesartan 150 mg twice a day; randomized, placebo-controlled trial, crossover study	Hypertensive and normotensive, microalbuminuria	128 type 2 DM	120 days	Irbesartan had a beneficial effect on reducing AER in both hypertensive and normotensive patients with type 2 diabetes	Sasso et al.[125]

AER, albumin excretion rate; DM, diabetes mellitus; ESRD, end-stage renal disease; S_{cr}, serum creatinine; UA:U_{cr}, urinary albumin-to-urinary creatinine ratio; UAE, urinary albumin excretion; UPE, urinary protein excretion.

TABLE 52-6 Effects of Antihypertensive Agents on Renal Blood Flow (RBF) and Glomerular Filtration Rate (GFR)

Antihypertensive Agents	Mechanism of Action	Effects on Renal Hemodynamics
Diuretics	Sodium and volume depletion	↓ GFR and RBF
	↑ Vasodilatory prostaglandin levels (IV loop diuretics)	↑ RBF
	Renal vasoconstriction (IV thiazide diuretics)	↓ GFR and RBF
β-Adrenergic blockers	↓ Cardiac output	↓ GFR and RBF
	↑ Renal vascular resistance (nonselective agents)	↓ GFR and RBF
	↑ Renal vascular resistance (β_1-selective agents)	No change in GFR and RBF
Centrally acting antiadrenergic drugs	↓ Renal vascular resistance (methyldopa)	No change in GFR and RBF
	↓ Renal perfusion pressure (clonidine, α_2-adrenergic agonist)	↓ GFR and RBF
Peripherally acting antiadrenergic drugs	Direct vasodilation (postsynaptic α_1-adrenoreceptor blocking agents)	No change in GFR and RBF
Direct vasodilator agents	↓ Renal vascular resistance (hydralazine, minoxidil)	↑ RBF and no effect on GFR
	Arterial vasodilation plus dilatation of venous capacitance vessels (nitroprusside)	↓ GFR and RBF (acute effect)
Calcium channel blockers		
Nondihydropyridine	↓ Renal vascular resistance by vasodilation of efferent arterioles (hypertensive patients)	↑ RBF and no change in GFR
Dihydropyridine (L-type)	↓ Renal vascular resistance by vasodilation of afferent arterioles (amlodipine, felodipine)	↑ RBF and ↑ GFR
Dihydropyridine (T-type)	↓ Renal vascular resistance by vasodilation of efferent arterioles (manidipine, efonidipine)	↑ RBF and no change in GFR
Renin-angiotensin-aldosterone system inhibitors (RAAS inhibitors)		
Angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, direct renin inhibitors.	↓ Renal vascular resistance by vasodilation of efferent arterioles	↑ RBF and no change in GFR[a]

↓, decrease; ↑, increase
[a]In some instances, may see a decrease in GFR with use of ACEIs and ARBs.

Effect of ACE inhibitors in diabetic and nondiabetic chronic renal disease: a systematic overview of randomized placebo-controlled trials, pages 695–707, Copyright © 2000, with permission from Elsevier.)*

CLINICAL CONTROVERSY

ACEI and ARBs have been advocated for treatment of hypertension in CKD for the reduction of proteinuria. Early studies suggested that a combination of ACEI and ARB may have additional benefit; however, recent data suggest that the combination may be associated with a higher incidence of adverse outcomes including frequent hyperkalemia and need for acute dialysis. However, many would still advocate for combined ACEI and ARB therapy for patients with overt proteinuria.

Studies suggest that no individual ACEI drug is truly superior to any other ACEI,[132] and the same holds true for ARBs.[145,146] For patients with hypertension, the primary goal is to optimally treat the blood pressure to target, and the secondary goal is to control proteinuria. For normotensive patients with microalbuminuria, one should titrate the ACEI/ARB to reduce the degree of microalbuminuria. However, patients with hypertension and proteinuria may still exhibit side effects associated with blood pressure lowering, and dosages should be titrated to the maximum reduction of proteinuria without reducing blood pressure to a level associated with adverse events including renal function compromise. Patients should be initiated on the lowest possible dose of ACEI/ARB and titrated to blood pressure control and proteinuria reduction. A specific recommendation regarding the dose to initiate therapy with a specific ACEI/ARB has not been established; consequently, the lowest recommended dose for the management of hypertension may be appropriate until such information is available. In addition, one needs to consider the presence of other concomitant diseases and past history of treatment, as well as any side effects demonstrated with particular agents. Generally, ACEIs are more cost-effective than ARBs because of the availability of generic formulations, and individual patient insurance coverage should be reviewed by the

clinician. If patients exhibit adverse effects such as cough and/or hyperkalemia, a switch to an ARB may be appropriate.

Because the clearance of all ACEIs (with the exception of fosinopril) is reduced in CKD, it is prudent to commence therapy at lower initial doses and subsequently titrate to achieve the optimal therapeutic effects and minimize potential toxicity. The antiproteinuric effects of ACEIs/ARBs are not necessarily attained at the same doses as the antihypertensive effects. Thus patients who have reached their blood pressure goals may require further dosage adjustments to achieve maximal reductions in urinary protein excretion. Serum potassium needs to be monitored when initiating therapy or changing doses with ACEIs or ARBs, especially when patients are concurrently receiving drugs that may increase the risk of hyperkalemia, such as nonsteroidal antiinflammatory agents. Chapter 19 has a thorough discussion of dose, dose titration, monitoring, and adverse effects of ACEIs and ARBs.

As noted above, the concept of aldosterone escape has led to the search for other methods in which to further suppress the renin-angiotensin-aldosterone system (RAAS) in an effort to improve renal outcomes. Spironolactone, a mineralocorticoid receptor blocker, can be added to ACEI/ARB therapy with careful monitoring since these patients would be at risk for hyperkalemia. An important systematic review of 15 studies including 8 randomized control trials evaluating spironolactone added to ACEI and/or ARB demonstrated a further reduction in proteinuria ranging from 15% to 54% with minimal hyperkalemic events.[147] Long-term data and information on preservation of renal function are still lacking, however. The newest agent of potential benefit is aliskiren, a direct renin inhibitor. This agent has been evaluated in three trials, two in combination with an ARB and one in combination with a diuretic.[148–150] Proteinuria was reduced in all of these studies although data regarding long-term benefit are lacking. The exact role of both these agents-whether to be used alone, with an ACEI or ARB, or added to ACEI/ARB combination-is still to be determined.

Some calcium channel blockers (CCBs) decrease glomerular injury without negatively changing renal hemodynamics.[128] The postulated mechanisms for this decrease in renal injury include suppression of glomerular hypertrophy, inhibition of platelet aggregation, and decrease in salt accumulation.[128] Although the data regarding dihydropyridine CCBs do not suggest any beneficial effects beyond those attributable to reducing blood pressure, there is some suggestion that the nondihydropyridine agents (diltiazem and verapamil) may have beneficial effects on proteinuria, although not as profoundly as ACEIs.[151] These agents are used occasionally in combination with ACEIs or ARBs, although data are limited to support this. In general, nondihydropyridine CCBs are used as second-line antiproteinuric drugs when ACEIs or ARBs are not tolerated. Efonidipine and manidipine, novel dihydropyridine CCBs that affect T-type calcium channels rather than L-type calcium channels, reduce intraglomerular pressure and may have antiproteinuric effects as well.[130,151] However, these drugs are not presently available in the United States, and how to best utilize these agents is not yet known.

Nondiabetic Chronic Kidney Disease

ANTIHYPERTENSIVE AGENTS

9 Reduction of blood pressure is key to decreasing cardiovascular and renal sequelae. However, all antihypertensive agents are not equal in their ability to preserve kidney function despite similar efficacy in terms of blood pressure reduction. Among the different antihypertensives available, ACEIs and ARBs are currently also considered the first choice for patients with nondiabetic CKD because they reduce intraglomerular pressure. Several short- and long-term clinical trials have assessed the effect of ACEIs on renal function for patients without diabetes; Table 52–7 summarizes these trials.[131,152–155] These studies vary in length from 12 weeks to 7 years, and

TABLE 52-7 Key Studies with Angiotensin-Converting Enzyme Inhibitors in Patients Without Diabetes

Drug, Dose, and Study Design	Baseline Characteristics	Number of Subjects and Disease	Duration	Outcomes	Reference and Study Name
Benazepril 10 mg once daily; randomized, placebo-controlled trial	Mild [GFR 46–60 mL/min (0.77–1.00 mL/s) Moderate [GFR 30–45 mL/min (0.50–0.75 mL/s)] renal insufficiency	583 Patients with various renal disorders including diabetes mellitus	3 years	Benazepril afforded a 53% risk reduction in primary end point of doubling of S_{cr} or requirement for dialysis; 71% and 46% risk reductions in the mild and moderate renal insufficiency groups, respectively	Maschio et al.[152]
Ramipril 2.5 mg once daily and titrated to BP; randomized, placebo-controlled trial	GFR 20–70 mL/min per 1.73 m^2 [0.19–0.67 mL/s/m^2] UPE ≥1 g/day	352 Proteinuric patients	5 years	Rate of loss of GFR was 0.89 mL/min per month in placebo group versus 0.39 mL/min per month in ramipril group; twice the numbers of patients receiving placebo versus ramipril reached primary composite end point of doubling of S_{cr} or ESRD	The GISEN Group[131]
Enalapril 20 mg once daily versus losartan 50 mg once daily; randomized trial	Proteinuria	93 Hypertensives	12 weeks	UP:Cr was reduced by 43% in losartan group versus 23% in enalapril group ($P = 0.05$)	Nielsen et al.[153]
Enalapril 5–40 mg daily versus other antihypertensive agents; randomized, controlled trial	UPE ≥0.5 g/day S_{cr} ≤1.5 mg/dL (≤132 µmol/L)	44 IgAN patients	7 years	Renal survival was significantly better in the enalapril group (100%) versus the other antihypertensive group (70%) after 4 years, and 92% versus 55% respectively, after 7 years; proteinuria significantly decreased in the enalapril group, whereas it tended to increase in the control group	Praga et al.[154]
Ramipril 1.25–5 mg daily versus conventional therapy; randomized controlled trial	Proteinuria 1–3 g/day	186 Chronic nephropathies	31 months	Progression to use ESRD was half as common in the ramipril group; patients with GFR ≤45 mL/min per 1.73 m^2 (0.43 mL/s/m^2) and proteinuria ≥1.5 g/24 hours had the greatest benefit from ramipril therapy	Ruggeneti et al.[155]

ESRD, end-stage renal disease; GFR, glomerular filtration rate; IgAN, immunoglobulin A nephropathy; S_{cr}, serum creatinine; UP:Cr, urinary protein-to-creatinine ratio; UPE, urinary protein excretion.

several enrolled a small number of subjects. Most patients had nephropathy associated with proteinuria and advanced CKD. Significant reductions in the risk of doubling serum creatinine, requirement for dialysis, and/or proteinuria were demonstrated for patients receiving the ACEIs. These studies and the summary results of a meta-analysis revealed that ACEIs conferred a 40% reduction in the risk of developing ESRD or doubling of serum creatinine for patients with overt proteinuria (>300 mg protein per 24 hours) and renal disease of various etiologies (see Fig. 52–3).[132] However, a meta-analysis failed to show a significant benefit of ACEI and/or ARBs over other antihypertensive agents in CKD progression.[133] A post hoc analysis of the African American Study of Kidney Disease and Hypertension (AASK), which evaluated two different blood pressure targets and three different treatment regimens in subjects with a GFR between 20 and 65 mL/min per 1.73 m^2 showed that the change in the level of proteinuria over 6 months of treatment predicted the progression of hypertensive CKD.[156] In addition, a post hoc analysis of the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), where hypertensive subjects were randomized to chlorthalidone, amlodipine, or lisinopril for a mean of 4.9 years, revealed similar incident rates of ESRD in the three treatment groups irrespective of the cause of renal disease.[157] Therefore, although the drug class versus absolute blood pressure reduction is an evolving area of investigation, current treatment guidelines recommend use of ACEI or ARBs in subjects with CKD.

The ARBs, although evaluated to a lesser extent than ACEIs, appear to have similar efficacy in terms of kidney protection for patients with several forms of glomerulonephritis (Table 52–8).[158,159] Proteinuria reduction on the order of 25% to 47% was shown with ARB therapy. However, these studies employed small numbers of patients with short follow-up time frames as compared with studies in diabetic patients. Despite these limitations, most clinicians use either ACEI or ARB therapy as the standard of care for patients with nondiabetic CKD and proteinuria. The combination use of ARBs with ACEIs, similar to data in diabetic kidney disease, results in a greater decrease in proteinuria than that seen with either agent alone.[160] The Combination Treatment of Angiotensin-II Receptor Blocker and Angiotensin-Converting Enzyme Inhibitor in Non-diabetic Renal Disease (COOPERATE) study prospectively evaluated the use of losartan 100 mg daily alone, trandolapril 3 mg daily alone, or the combination of the two in 336 patients with nondiabetic kidney diseases. The primary end point, time to doubling of serum creatinine or ESRD, was observed in 11% of combination therapy patients and in 23% of each of the single-agent treatment groups.[161] However, this study has drawn several criticisms.[162,163] In light of the ONTARGET study findings above,[142] combination therapy may be dangerous and perhaps is best used in the setting of overt proteinuria and with close supervision. The selection of ACEIs versus ARBs in the control of proteinuria in nondiabetic kidney disease is essentially predicated on cost of therapy, patient tolerance, and clinician preference. As with diabetic kidney disease, modulation of RAAS with mineralocorticoid blockers, such as spironolactone,[147] and perhaps the direct renin inhibitor, aliskiren, may have a role in kidney disease with overt proteinuria.

The CCBs are also effective treatments for hypertension for patients with nondiabetic CKD. However, as was mentioned previously, only the nondihydropyridine CCBs have been studied and shown to reduce the rate of decline of kidney function. There are currently no data to suggest that higher doses of nondihydropyridine CCBs are needed to elicit a reduction in proteinuria as compared with a reduction in blood pressure. The role of dihydropyridine T-type CCBs remains uncertain.

Although diuretics are commonly used to treat fluid overload and hypertension for patients with CKD, there are minimal data to suggest any renal protection in terms of proteinuria regression or a reduction in the rate of progression. A single randomized, controlled trial has demonstrated an additive benefit of hydrochlorothiazide, a thiazide diuretic, to an ACEI regimen in reducing proteinuria in nondiabetic proteinuric kidney disease.[164] Chapter 58 addresses the use of diuretics for managing volume overload. Other available antihypertensive agents are used to control blood pressure in patients with kidney disease. Additional central and peripherally acting antihypertensive agents can be used for patients with CKD. One must consider the need for dosage reductions caused by decreases in GFR for drugs that are excreted by the kidneys and/or supplemental doses as a consequence of dialysis removal of hydrophilic β-blockers such as nadolol, acebutolol, and atenolol.

Regardless of the treatment regimen, hypertension should be treated to the currently accepted targets for patients with CKD. If proteinuria is present, the use of ACEIs, ARBs, and possibly nondihydropyridine CCBs may be superior to conventional agents in decreasing proteinuria and glomerular hypertension.

As precipitous reductions in blood pressure may be deleterious to kidney function for patients with underlying CKD, blood pressure targets in these patients should be achieved over several weeks to allow the kidney to adapt to reduced perfusion pressures.[108] Typically there is an acute but sustained reduction in GFR of approximately 25% to 30% within 3 to 7 days after initiation of ACEI therapy as a result of a reduction in intraglomerular pressure.[165] If a sustained increase in the serum creatinine by more than 30% after ACEI therapy initiation is observed, reduction of the dose or even discontinuation of ACEI therapy should be strongly considered (see Chap. 55). It is necessary to realize that although ACEI therapy may be effective in reducing the rate of nephropathy progression, one needs to consider their propensity for hyperkalemia and potential for acute GFR reduction especially for patients who already have compromised GFR.

TABLE 52-8 Key Studies with Angiotensin Receptor Blockers in Patients Without Diabetes

Drug, Dose, and Study Design	Baseline Characteristics	Number of Subjects and Disease	Duration	Outcomes	Reference
Losartan 50 mg once daily versus control	Normotensive, proteinuria	23 FSGS patients	1 year	Proteinuria decreased 47% in the losartan group at 1 year, while there was a significant increase in proteinuria in the control group; total serum protein and albumin concentrations also increased in the losartan group; cholesterol levels of the losartan group were significantly reduced	Usta et al.[158]
Losartan 25 mg once daily versus enalapril 10 mg once daily; randomized, controlled trial	GFR 36–93 mL/min	34 Primary glomerulonephritis	3 months	Proteinuria reduced 25% versus 45% in losartan and enalapril groups, respectively; significant decline in GFR in enalapril group and no change in losartan group	Tylicki et al.[159]

FSGS, focal segmental glomerulosclerosis; GFR, glomerular filtration rate; UPE, urinary protein excretion.

CLINICAL CONTROVERSY

Some clinicians fail to prescribe ACEI or ARB medications when the GFR is less than 20 to 30 mL/min per 1.73 m^2 because they fear the patient may develop a further elevation in serum creatinine, whereas other clinicians prescribe these medications and evaluate serum creatinine closely after therapy initiation and dosage increases.

Other Interventions to Limit Disease Progression

⑩ Other interventions such as lipid-lowering regimens and anemia management have been suggested to slow the progression of CKD.

Hyperlipidemia Treatment Although several drugs are available for lipid lowering, the β-hydroxy-β-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors, or statins, and gemfibrozil have been most often used in dyslipidemic patients with CKD with and without proteinuria.[166] The primary goal of treatment is to decrease the risk for progressive atherosclerotic cardiovascular disease. Additionally, a prior meta-analysis of 13 studies of lipid-lowering agents also showed a reduction in the rate of CKD progression by 0.156 mL/min per month.[167] Mechanisms for this effect are unknown, but statins may reduce proteinuria, inflammation and fibrosis.[168] In animal models of hyperlipidemia and kidney disease, lipid-lowering agents can decrease the extent of glomerular injury.[169] Recent clinical data have provided less certainty. A post hoc analysis of the ALLHAT[170] demonstrated no difference in ESRD rates among those treated with pravastatin versus those treated with usual care. A Cochrane systematic review demonstrated a decline in proteinuria and all-cause cardiovascular mortality but no attenuation of the decline of renal function.[168] However, this would not preclude appropriate treatment of hyperlipidemia. Additional therapies that show favorable benefits on lipids are cholestyramine, carnitine, fish oil, low-molecular-weight heparins, and exercise.[171,172] The National Cholesterol Education Program III and NKF K/DOQI guidelines should be consulted for a thorough review of lipid reduction and cardiovascular disease for patients with CKD.[83,173] Therefore, treatment of lipid abnormalities for patients with CKD may have a beneficial effect on slowing the rate of progression of the kidney disease.

Anemia Treatment Prolonged anemia is associated with left ventricular hypertrophy and heart failure. It has been suggested that anemia may increase the rate of CKD progression.[174] Researchers have coined the phrase "cardiorenal anemia syndrome" to describe the interrelationship between anemia, heart failure, and CKD.[174] Tissue hypoxia associated with anemia could be a stimulus for continued renal injury in those with stages 3 to 5 CKD. Although, at present, no definitive studies have been performed, some have hypothesized that the treatment of heart failure and anemia may reduce the progression of both heart failure and CKD.[175] Chapter 53 discusses anemia as a complication of CKD.

PHARMACOECONOMIC CONSIDERATIONS

The financial and societal costs of the care of individuals with CKD are disproportionately high. Excluding those with ESRD, patients with CKD comprise less than 10% of the Medicare population, yet account for nearly 28% of Medicare expenditures or over $57 billion.[2] These statistics suggest that the spectra of CKD is responsible for nearly one third of total Medicare expenditures.

There have been several evaluations of the potential pharmacoeconomic impact of screening for microalbuminuria in various populations. Generally speaking, the cost-effectiveness of screening is most apparent when targeted to high-risk populations including those with hypertension or diabetes or those over the age of 60.[176–178] When applied to diabetes, screening actually appears to have associated cost savings.[177,178] When compared with other conventional measures, such as screening for cervical cancer, screening for proteinuria in appropriate populations is similar or more favorable.[178] Intensive management of diabetes and hypertension beyond screening also appear to cost-effective.[177] As a caveat, these analyses employ simulated models whose results remain to be prospectively confirmed.

With regard to choice of pharmacologic agent, the majority of focus has been on agents employed in RAAS blockade. Both ARBs and ACEIs have been evaluated in the setting of diabetic kidney disease and appear to be favorable from the standpoint of cost and quality-adjusted life years gained.[176,177] ACEIs have demonstrated similar cost benefit in nondiabetic kidney disease.[179] One study provides data to suggest that even the more novel and expensive direct renin inhibitor, aliskiren, may have an beneficial cost profile in hypertensive diabetics with proteinuria.[180] In summary, screening and optimal therapy with intensive glycemic control and RAAS blockade may limit progression to ESRD and death with reasonable costs to society.

CONCLUSIONS

DIABETICS

Based on the available clinical and experimental data, pharmacologic interventions can help to limit the progression of CKD in diabetic patients. Figure 52–4 summarizes these interventions. All patients with type 1 diabetes for a duration of more than 5 years and all type 2 diabetics should be screened yearly for microalbuminuria (urinary albumin excretion or urinary albumin-to-creatinine ratio).[106] Blood glucose should be maintained within or close to the normal range by frequent insulin doses or by using a continuous subcutaneous insulin infusion while minimizing the risk of hypoglycemia by frequent blood glucose monitoring.[106] ACEI therapy should be initiated in normotensive and hypertensive type 1 or type 2 diabetic patients with persistent microalbuminuria (30 to 300 mg/day) or overt albuminuria (greater than 300 mg/day). ACEIs should be titrated every 1 to 3 months to achieve a maximal reduction in urinary albumin excretion. Within 1 week of initiating or increasing the dose of an ACEI, serum creatinine and potassium should be evaluated to detect abrupt reductions in GFR or development of hyperkalemia. ARBs should be considered as another first-line therapy for type 2 diabetic patients for the reduction of persistent proteinuria or albuminuria. A nondihydropyridine CCB may be an effective secondary alternative agent for patients who are unable to tolerate either an ACEI or an ARB. A combination of an ACEI with an ARB may result in a greater reduction in proteinuria or albuminuria than either agent alone and thus may be a therapeutic alternative for patients who are not maximally responding to single-agent therapy. Addition of an aldosterone receptor blocker may be considered in subjects with documented aldosterone escape. Direct renin inhibition represents a novel approach whose role is still to be determined.

NONDIABETIC PATIENTS

Figure 52–5 summarizes therapeutic interventions for nondiabetic patients with CKD. Nutritional management should be monitored frequently, regardless of the amount of protein intake prescribed,

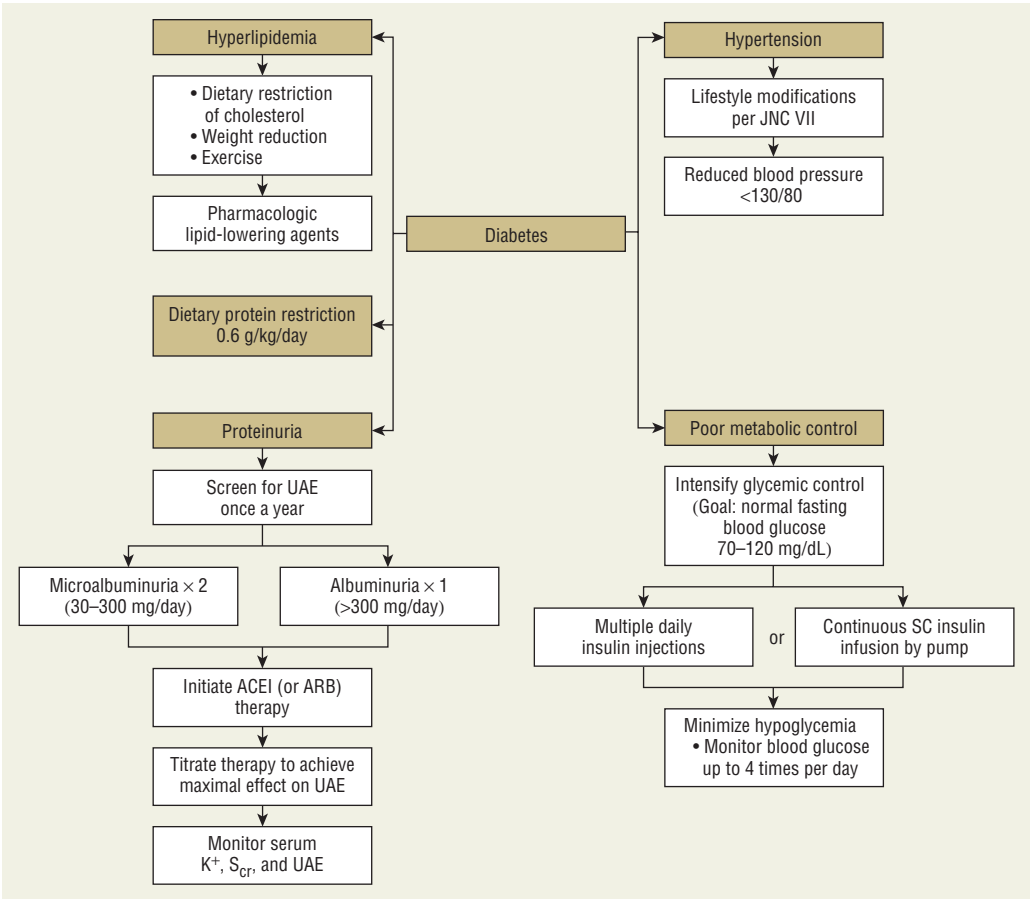

FIGURE 52-4. Therapeutic strategies to prevent progression of renal disease in diabetic individuals. (ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; UAE, urinary albumin excretion; SC, subcutaneous).

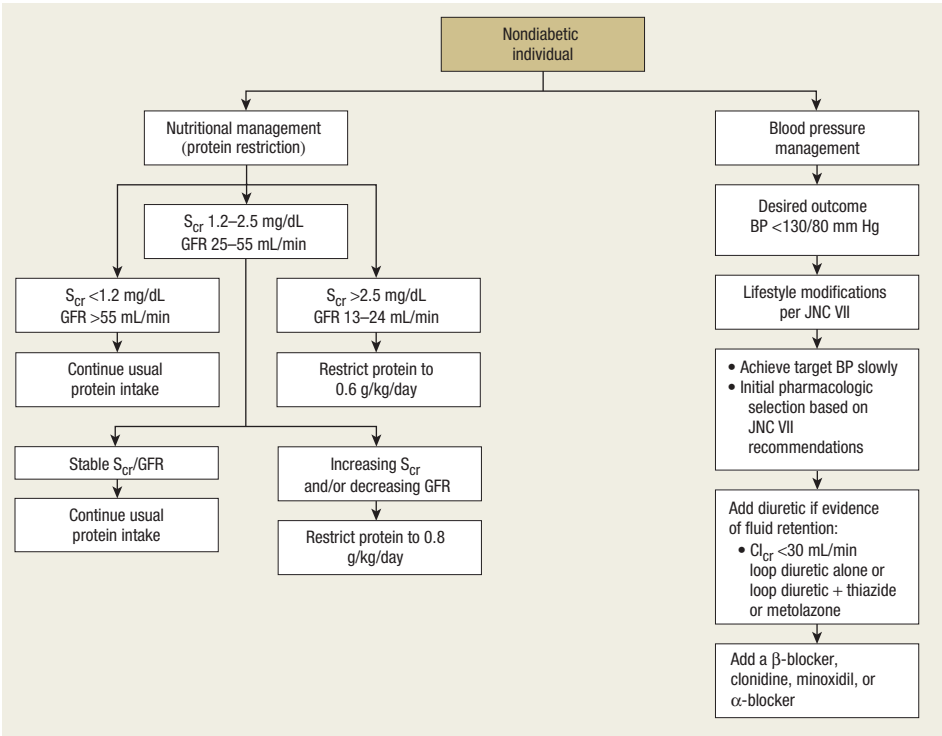

FIGURE 52-5. Therapeutic strategies to prevent progression of renal disease in nondiabetic individuals. (*ACEI,* angiotensin-converting *enzyme* inhibitor; ARB, angiotensin receptor blocker; BP, blood pressure; *GFR, glomerular filtration rate;* CL_{cr}, *creatinine clearance;* MAP, *mean arterial pressure;* S_{cr}, serum creatinine.

to avoid malnutrition. Based on the results of the MDRD study, a low-protein diet is of variable benefit for patients with moderate kidney dysfunction [GFR 25 to 55 mL/min per 1.73 m^2]. Thus it is probably reasonable to prescribe a standard-protein diet unless the patient develops rapid progression of their kidney disease. For patients with severe kidney dysfunction, as defined by the MDRD study as a GFR of 13 to 24 mL/min per 1.73 m^2, a low-protein diet of 0.6 g/kg per day may reduce the rate of decline in kidney function, the time to reach end-stage kidney disease, and the onset of uremic symptoms.[96]

Blood pressure control should target normotensive levels of less than 130/80 mm Hg for patients with CKD.[108] For patients with proteinuria above 3 g/day and CKD, an ACEI or ARB is still considered to be first-line therapy. Hyperlipidemia should also be treated to decrease cardiovascular risks.

As kidney function decreases and subjects approach CKD stage 4, the patient should begin to get prepared for renal replacement therapy. Hemodialysis, peritoneal dialysis, and renal transplantation need to be discussed (see Chapters 54 and 98). Early referral to a nephrologist or other clinician specializing in the care of patients with progressive CKD may allow the proper dialysis vascular access placement and the evaluation for uremia symptoms and may allow for identification and treatment of the complications including anemia and metabolic abnormalities.[181]

ABBREVIATIONS

ACEI: angiotensin-converting enzyme inhibitor

ARB: angiotensin receptor blocker

CCB: calcium channel blocker

CKD: chronic kidney disease

CRIC: Chronic Renal Insufficiency Cohort

DCCT: Diabetes Control and Complications Trial

ESRD: end-stage renal disease

GFR: glomerular filtration rate

HMG-CoA: β-hydroxy-β-methylglutaryl coenzyme A (reductase)

K/DOQI: Kidney Dialysis Outcomes and Quality Initiative

KEEP: Kidney Early Evaluation Program

MAP: mean arterial blood pressure

MDRD: Modification of Diet in Renal Disease

NHANES: National Health and Nutritional Examination Survey

UKPDS: United Kingdom Prospective Diabetes Study

USRDS: United States Renal Data System

CHAPTER 53

Chronic Kidney Disease: Management of Complications

JOANNA Q. HUDSON

KEY CONCEPTS

1. The number of patients with chronic kidney disease (CKD) is increasing, and it is expected that the number of patients with end-stage renal disease (ESRD) will exceed 780,000 by the year 2020.
2. Common complications of stages 4 and 5 CKD include anemia, CKD–mineral and bone disorder (MBD) and renal osteodystrophy, fluid and electrolyte abnormalities, metabolic acidosis, and malnutrition.
3. Anemia of CKD, which is primarily caused by a deficiency in the production of endogenous erythropoietin by the kidney, is a common complication observed in patients with stages 4 and 5 CKD.
4. CKD-MBD and renal osteodystrophy are common in patients with CKD and contribute to extravascular calcifications and an increased risk of cardiovascular mortality.
5. Cardiovascular complications are prevalent in the CKD population and are the leading cause of mortality in patients with ESRD. Thus at the initiation of dialysis, all ESRD patients should be assessed for cardiovascular disease, which includes assessment for coronary artery disease, cardiomyopathy, valvular heart disease, cerebrovascular disease, and peripheral vascular disease in addition to screening for both traditional and nontraditional cardiovascular risk factors.
6. The management of CKD and the associated secondary complications should be initiated prior to development of ESRD.
7. Guidelines by the National Kidney Foundation Kidney Disease/Dialysis Outcomes Quality Initiative (NKF-K/DOQI) and Kidney Disease: Improving Global Outcomes (KDIGO) provide information to assist health care providers in clinical decisions and the design of appropriate therapy to manage complications.
8. Patient education plays a critical role in the appropriate management of patients with stage 4 or 5 CKD and related complications. A multidisciplinary team structure is a rational approach to provide this education and effectively design and implement the extensive nonpharmacologic and pharmacologic interventions required.
9. Management of anemia includes administration of erythropoietic-stimulating agents (ESAs) (epoetin alfa and darbepoetin alfa) and regular iron supplementation (oral or intravenous administration) to achieve a target hemoglobin of 11 to 12 g/dL (110–120 g/L; 6.83–7.45 mmol/L). There is now evidence indicating a higher risk of cardiovascular events when hemoglobin is targeted to greater than 12 g/dL (120 g/L; 7.45 mmol/L).
10. Management of CKD-MBD includes dietary phosphorus restriction, prudent use of phosphate-binding agents, vitamin D, and calcimimetic therapy.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

The clinical syndrome that develops insidiously as kidney function declines to stages 4 and 5 chronic kidney disease (CKD), begins with nonspecific symptoms such as nausea and vomiting, which become progressively worse as the glomerular filtration rate (GFR) drops below 15 mL/min/1.73 m^2 (0.14 mL/s/m^2). At this level of GFR renal replacement therapy, either dialysis (see Chap. 54) or transplantation (see Chap. 98), is indicated. The patient with stage 5 CKD requiring chronic dialysis or renal transplantation is said to have end-stage renal disease (ESRD). In this chapter, *ESRD* refers specifically to patients who are receiving chronic dialysis.

The staging system for CKD was primarily designed to help clinicians identify individuals in need of appropriate interventions to delay progression of CKD, as discussed in Chapter 52.[1] Often complications of CKD are unrecognized or are inappropriately managed, and for many patients this contributes to significant morbidity, premature mortality, or a poor prognosis by the time they reach ESRD.[2] The most frequent complications of CKD include fluid and electrolyte abnormalities, anemia, CKD-related mineral and bone disorder (CKD-MBD) and renal osteodystrophy, hypertension, hyperlipidemia, and metabolic acidosis. Miscellaneous complications resulting from the effects of CKD on other organ systems also occur. Table 53–1 lists other complications of CKD that are not specifically covered in this chapter. Cardiovascular disease is also common in patients with CKD and requires early and aggressive intervention.[3] This chapter discusses the epidemiology of CKD and the pathophysiology and pharmacotherapeutic management of the complications and comorbidities that occur frequently in adult patients with stage 4 and 5 CKD.

EPIDEMIOLOGY

1. Approximately 26 million people in the United States are estimated to have CKD, a number that has increased in the last 2 decades as the prevalence of diabetes and hypertension has

TABLE 53-1 Other Complications of Chronic Kidney Disease

Organ System or Complication	Effects
Amyloidosis	Accumulation of β_2-microglobulin Manifests as carpal tunnel syndrome
Uremic bleeding	Potentially a result of platelet abnormalities
Endocrine	Thyroid function—symptoms of hypothyroidism Hypothermia Glycemic control—↑ in hypoglycemic episodes as kidney disease progresses (result of ↓ degradation of insulin by the kidney)
Gastrointestinal	Nausea, vomiting, diarrhea, anorexia, GI bleeding
Immune system	Impaired cell-mediated immunity Lymphopenia
Neurologic	Peripheral neuropathies Restless leg syndrome Uremic encephalopathy

increased.[4] The 2009 report of the United States Renal Data System (USRDS), indicates that in 2007, the latest year for which data are available, a total of 111,000 new cases of ESRD were reported (incidence) and the number of individuals with ESRD (prevalence) as of the end of 2007 was 527,283, including 368,544 patients on dialysis and 158,739 with a functioning kidney after transplantation.[2] Incidence rates of ESRD are higher in African Americans (3.7 times greater) and Native Americans (1.8 times greater) compared with whites, a trend that has persisted over the last decade. The incidence in Hispanics is 1.5 times greater than that observed in non-Hispanics.[2] The incident rate has also increased dramatically in patients 65 years of age and older over the last decade and the prevalence has increased 24% since 2000. Although the overall number of patients with ESRD is substantial now, it is projected that by the year 2020 the number will exceed 780,000 patients, with the majority of cases attributable to diabetes. Total Medicare costs for ESRD in 2007 were approximately $24 billion, a 6.1% increase from the previous year, which accounted for 5.8% of the total Medicare budget in 2007.[2]

The mortality rate in the ESRD population increases substantially with age and is much greater than age-matched individuals in the general population for every age group. In fact, ESRD patients have a mortality rate 7 to 8.5 times higher than age-matched individuals without kidney disease.[2] Associated predictors of mortality and hospitalization in hemodialysis patients include decreased serum albumin, elevated phosphorus, low hemoglobin level, catheter use for dialysis access, and the presence of comorbidities, such as diabetes and cardiovascular disease.[2,5] The association of mortality with these factors highlights the need to address complications as soon as they are detected, ideally prior to development of ESRD.

CKD was identified as one of the public health priorities for the nation in the Healthy People 2010 and the Healthy People 2020 disease prevention and health promotion objectives.[6,7] The proposed goals of this 2020 initiative as it relates to CKD are as follows: (a) reduce the rate of new cases of ESRD, (b) reduce deaths in persons with ESRD, (c) increase the proportion of CKD patients receiving care from a nephrologist at least 12 months before the start of renal replacement therapy, (d) reduce kidney failure due to diabetes, (e) increase the proportion of persons with diabetes and CKD who receive recommended medical evaluation and who receive medical treatment with angiotensin-converting enzyme inhibitors or angiotensin II receptor blockers, (f) improve cardiovascular care in persons with CKD, (g) reduce the percentage of the U.S. population with CKD, (h) reduce the death rate among people with CKD, and (i) increase the percentage of persons with CKD who know they have impaired renal function.[6,7]

ETIOLOGY

Many clinical conditions and diseases lead to progressive kidney damage and ESRD (see Chaps. 52 and 56). Diabetes mellitus continues to be the leading cause of CKD and ultimately of ESRD in the United States, accounting for 54% of new ESRD cases in 2007.[2] Hypertension, as the second leading cause of ESRD in the United States, accounts for approximately 33% of new cases of ESRD.[2] Glomerulonephritis, which includes a wide variety of lesions caused by immunologic, vascular, and other idiopathic diseases (see Chap. 56) is the third leading cause of ESRD in the United States. Other diseases and conditions causing CKD are cystic kidney disease, Wegener granulomatosis, vascular diseases, and acquired immunodeficiency syndrome (AIDS) nephropathy.

PATHOPHYSIOLOGY

Progression of CKD to ESRD occurs over years to decades in the majority of cases, with the precise mechanism of kidney damage dependent on the etiology of the disease (see Chaps. 52 and 56). The consequences and complications of marked reductions in kidney function are fairly uniform irrespective of the underlying etiology. The mechanisms of progression of CKD and measures to delay progression are essential elements for primary care clinicians to consider as they design intervention strategies for their patients. Those clinicians who care for patients with ESRD or stages 4 and 5 CKD must also have a clear understanding of the pathogenesis, clinical presentation, and management strategies for secondary complications and comorbidities to improve quality of care and outcomes.

No single toxin is responsible for all of the signs and symptoms of uremia observed in patients with stage 4 or 5 CKD. Accumulation of one or several of these known and potential toxins may be the result of increased secretion, as with the biologically active substances such as parathyroid hormone (PTH) and atrial natriuretic peptide; decreased clearance because of reduced metabolism within the kidney for compounds such as PTH, gastrin, growth hormone, glucagon, somatostatin, prolactin, calcitonin, and insulin; and/or decreased renal clearance of metabolic by-products of protein metabolism. The buildup of these uremic toxins ultimately results in altered organ and immune function and leads to a myriad of secondary complications.

2 Altered fluid and electrolyte homeostasis, metabolic acidosis, anemia of CKD, CKD-MBD and renal osteodystrophy, and cardiovascular disease are among the common complications associated with a substantial decline in GFR. The pathophysiology of these complications is described here.

FLUID AND ELECTROLYTE ABNORMALITIES

Sodium and Water

In persons with normal kidney function, sodium balance is maintained at a sodium intake of 120 to 150 mEq/day (120–150 mmol/day). The fractional excretion of sodium (FE_{Na}) ranges from approximately 1% to 3% (see Chap. 58 for more information). Water balance is also maintained with a normal range of urinary osmolality of 50 to 1,200 mOsm/kg (50–1,200 mmol/kg); average range 500–800 mOsm/kg [500–800 mmol/kg]. In most

individuals with CKD and stable kidney function, total body sodium and water increase modestly, but may not be clinically obvious. Free water clearance is generally maintained until the more advanced stages of CKD when patients have a reduced ability to concentrate or dilute their urine. In patients with severe CKD (stages 4 and 5), serum sodium concentration is generally maintained as the result of an increase in FE_{Na} by as much as 30%, but results in a volume-expanded state.[8] Significant sodium retention is more common when the GFR is less than 10 mL/min./1.73 m^2 (0.10 mL/s/m^2). Volume overload with pulmonary edema can result, but the most common manifestation of increased intravascular volume is hypertension, which may further contribute to progressive kidney damage.

Individuals with CKD may also have impaired ability to conserve sodium and water. As a result they are prone to develop prerenal acute kidney injury when conditions of volume depletion occur (e.g., vomiting, blood loss, diarrhea, etc.). Thus FE_{Na} and urine osmolality may be less useful in patients with advanced CKD who develop acute on chronic CKD to differentiate prerenal from an intrinsic acute kidney injury.

Potassium Homeostasis

Serum potassium is freely filtered at the glomerulus, reabsorbed in the proximal tubule and loop of Henle, and actively secreted into the urine at the cortical collecting duct. The kidneys normally excrete 90% to 95% of the daily potassium dietary load. The fractional excretion of potassium (FE_K) is approximately 25% (0.25) (see Chap. 60). Normally only 5% to 10% of ingested potassium is excreted through the gut. Potassium homeostasis is also maintained by shifting extracellular potassium intracellularly immediately following ingestion of a potassium load. In patients with CKD, potassium balance is maintained by an increase in distal tubular potassium secretion in which aldosterone plays an important role; FE_K can increase to as high as five times normal.[8] Thus the serum potassium concentration is usually maintained in the normal range until the GFR is less than 20 mL/min/1.73 m^2 (0.19 mL/s/m^2), at which point mild hyperkalemia is likely to develop. Mild elevations are observed in stage 3 CKD, but more significant (and life-threatening) elevations are likely to be observed in those with stage 4 and 5 CKD. A significant increase in potassium secretion by the colon also contributes to the maintenance of potassium balance, but this adaptation cannot compensate fully for the decrease in renal potassium excretion that occurs with advanced kidney disease.

METABOLIC ACIDOSIS

Individuals with normal kidney function generate enough hydrogen ion to reclaim all filtered bicarbonate and to secrete approximately 1 mEq/kg per day (1 mmol/kg per day) of hydrogen ions, which are generated from the metabolism of dietary proteins (see Chap. 61). As a result, a constant body fluid pH is maintained through the buffering of hydrogen ion by proteins, hemoglobin, phosphate, and bicarbonate. Renal ammoniagenesis and phosphate excretion buffer the urine and facilitate acid excretion. In advanced CKD, all filtered bicarbonate is reclaimed, but the ability of the kidneys to synthesize ammonia is impaired. This decrease in urinary buffer results in decreased net acid excretion and continuous positive hydrogen ion balance; consequently, metabolic acidosis develops. Clinically significant metabolic acidosis is commonly seen when the GFR drops below 30 mL/min/1.73 m^2 (0.29 mL/s/m^2) (stage 4 CKD) and the plasma bicarbonate concentration tends to stabilize at 15 to 20 mEq/L (15 to 20 mmol/L). Treatment is required to maintain the bicarbonate at the recommended target of 22 mEq/L (22 mmol/L) in this population.[9]

ANEMIA OF CHRONIC KIDNEY DISEASE

❸ The primary cause of anemia in CKD patients is a decrease in production of erythropoietin by the proximal tubular cells of the kidney, where approximately 90% of production occurs. Plasma concentrations of erythropoietin increase exponentially in response to decreased oxygenation in individuals with normal kidney function as hemoglobin and hematocrit decline. In contrast, there is no correlation between the degree of anemia and erythropoietin concentrations in anemic ESRD patients. The result is a normochromic (normal colored red cell), normocytic (normal size red cell) anemia.[10] There is a strong correlation between the prevalence of anemia and the stage of CKD, with prevalence estimates of approximately 50% in stage 4 CKD and 75% for stage 5 CKD patients at the start of dialysis.[10]

Iron demands increase when red blood cell production is stimulated by an erythropoietin stimulating agent (ESA) such as epoetin alfa; therefore, iron deficiency is common in individuals with CKD and is the leading cause of resistance to ESAs. Iron supplementation is often necessary to correct and prevent iron deficiency. Hepcidin is a hormone produced by the liver that is responsible for regulation of iron. This hormone directly inhibits the protein ferroportin that transports iron out of storage cells. When iron stores are high, hepcidin production is increased to block the transfer of iron from enterocytes to the plasma. Conversely hepcidin production is decreased when iron stores are low. Hepcidin production is also induced by inflammation or infection. As a result the increase in hepcidin in inflammatory conditions may lead to a sequestering of iron and ineffective red blood cell production (e.g., iron-restricted erythropoiesis). The fact that hepcidin plays such a role in iron regulation has prompted the development of hepcidin antagonists to potentially alter iron transport.[11]

Additional factors contributing to the development of anemia of CKD are the decreased red cell life span (from the normal of 120 days to approximately 60 days in individuals with stage 5 CKD), vitamin B_{12} and folate deficiencies, and blood loss from regular laboratory testing and hemodialysis for patients requiring this modality of renal replacement therapy. A schematic of the process of red blood cell production is shown in Figure 53–1 that includes factors that impair this process in individuals with CKD.[12]

Anemia in the CKD population has been associated with decreased quality of life, increased hospitalizations, and cardiovascular disease.[13,14] ESAs have been shown to reduce these morbidities; however, there is now increasing evidence that treatment of anemia to hemoglobin targets above 12 g/dL (120 g/L; 7.45 mmol/L) may lead to increased risk of cardiovascular events and death.[15,16] Thus treatment approaches have shifted to less aggressive use of ESAs and more conservative goals for Hb in the CKD population.[17]

CKD-MINERAL AND BONE DISORDER (CKD-MBD) AND RENAL OSTEODYSTROPHY

❹ Disorders of mineral and bone metabolism are common in the CKD population and include abnormalities in parathyroid hormone (PTH), calcium, phosphorus, the calcium-phosphorus product, vitamin D and bone turnover, as well as soft tissue calcifications. Historically these abnormalities have been described as classic characteristics of secondary hyperparathyroidism and renal osteodystrophy *(ROD)*. Recently the term *CKD-mineral and bone disorder* (*CKD-MBD*) has been advocated to encompass the abnormalities in mineral and bone metabolism as well as associated calcifications.[18]

The pathophysiology of CKD-MBD is complex (Fig. 53–2). Calcium and phosphorus homeostasis is mediated through the effects of four hormones on bone, the GI tract, kidney, and parathyroid gland. These hormones include PTH, the precursor

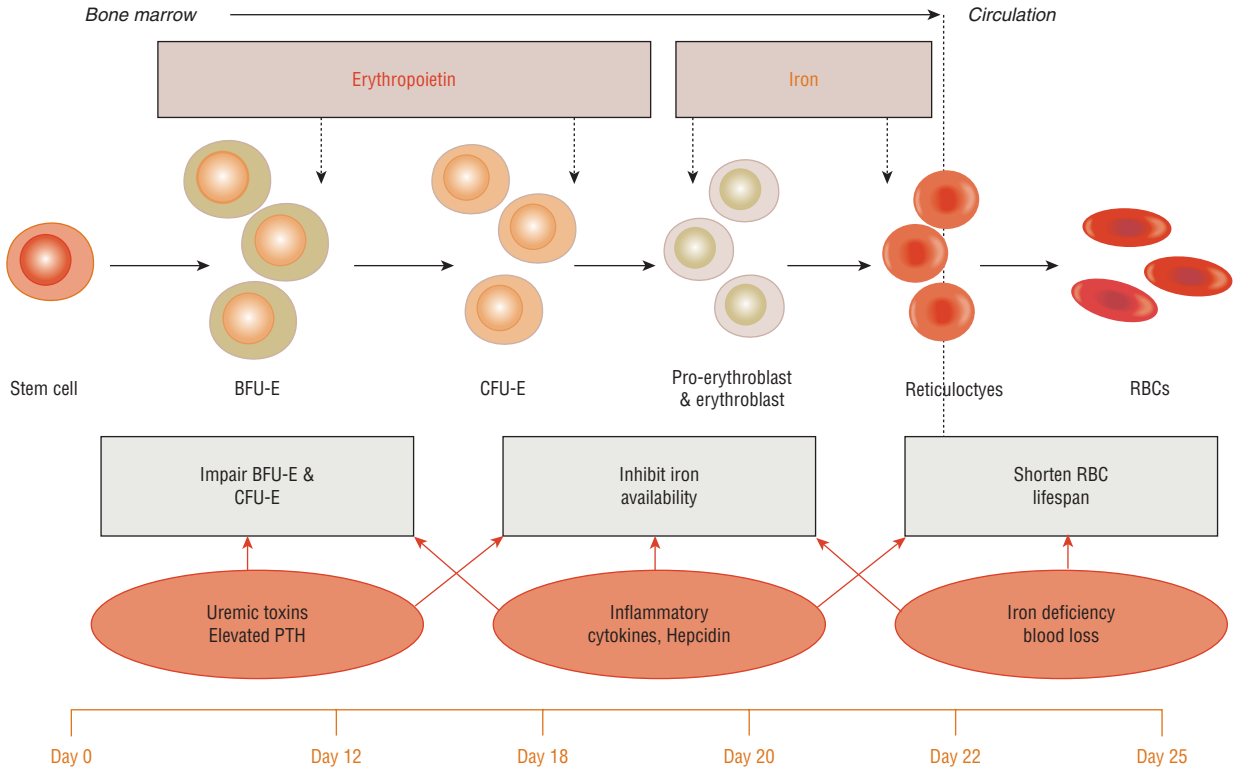

FIGURE 53-1. The process of red blood cell production (erythropoiesis) in the bone marrow requires erythropoietin and iron. This process is impaired due to factors that occur in advanced CKD such as accumulation of uremic toxins and inflammation (shown in the rectangles and ovals). (BFU-E, burst-forming unit erythroid; CFU-E, colony-forming unit erythroid; RBC, red blood cells.) (*Reprinted from Adv Chronic Kidney Dis, Vol. 16:2, Kalantar-Zadeh, et al., Intravenous Iron Versus Erythropoiesis-Stimulating Agents: Friend or Foe in Treating Chronic Kidney Disease Anemia?, 143, Copyright © 2009, with permission from Elsevier.*)

form of vitamin D known as 25-hydroxyvitamin D (25-OHD), active vitamin D or 1,25-dihydroxyvitamin D (calcitriol), and fibroblast growth factor-23 (FGF-23). As kidney function declines there is a decrease in phosphorus elimination, which results in hyperphosphatemia and a reciprocal decrease in serum calcium concentration. Hypocalcemia is the primary stimulus for secretion of PTH by the parathyroid glands. PTH secretion is suppressed by the interaction of ionized calcium with the calcium-sensing receptor on the chief cells of the parathyroid gland. Hyperphosphatemia also increases PTH synthesis and release through its direct effects on the parathyroid gland and production of prepro-PTH messenger RNA.[19] In an attempt to normalize ionized calcium, PTH decreases

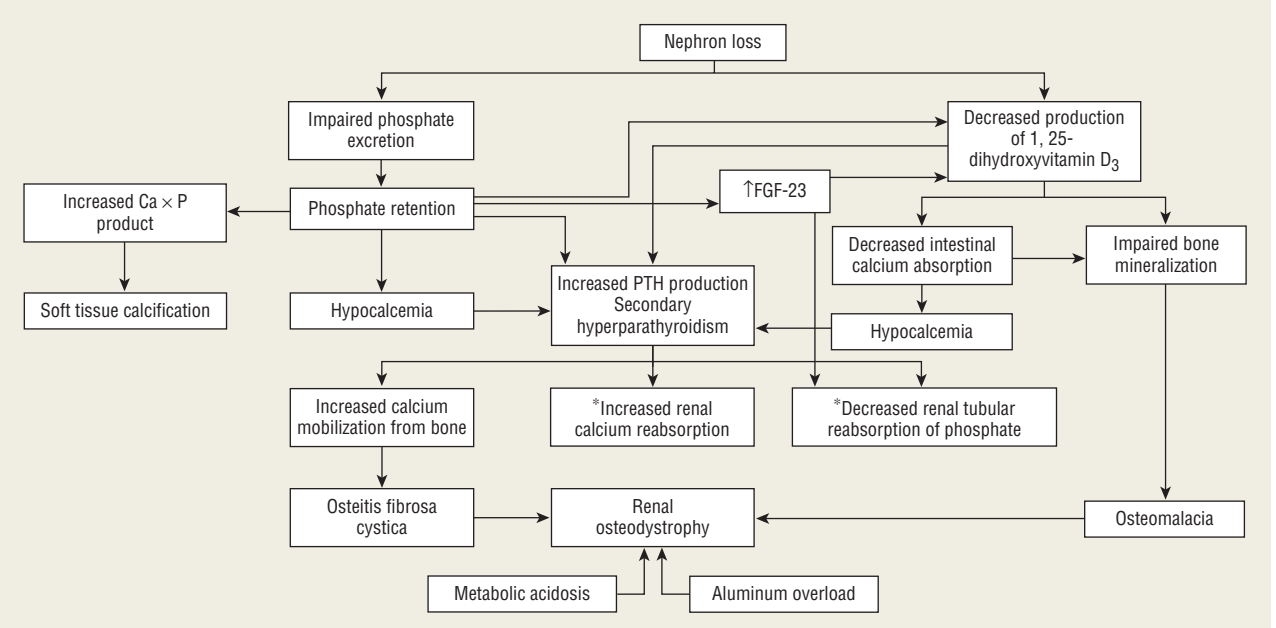

FIGURE 53-2. Pathogenesis of CKD-MBD and renal osteodystrophy. (*These adaptations are lost as kidney disease progresses.)

phosphorus reabsorption and increases calcium reabsorption by the proximal tubules of the kidney (at least until the GFR falls to less than approximately 30 mL/min) and also increases calcium mobilization from bone. FGF-23 production in bone also increases and promotes phosphate excretion by the kidney. The result is a resetting of the calcium and phosphorus homeostasis set point, at least in the early stages of CKD; however, this occurs at the expense of an elevated PTH ("the trade-off hypothesis"). With advanced kidney disease the kidney fails to respond to PTH or to FGF-23. The increase in PTH is most notable when GFR is less than 60 mL/min/1.73 m^2 (0.58 mL/s/m^2) (stage 3 CKD) and worsens as kidney function further declines.[20] Elevated PTH levels have been reported in approximately 21% of patients with an estimated GFR between 60 and 69 mL/min/1.73 m^2 (0.58 and 0.66 mL/s/m^2)and in 56% of patients with stage 3, 4, or 5 CKD.[20]

The most active form of vitamin D (1,25-dihydroxyvitamin D_3 or calcitriol) promotes increased intestinal absorption of calcium, which helps to normalize ionized calcium. Calcitriol also works directly on the parathyroid gland to suppress PTH production. The enzyme 1 α-hydroxylase is responsible for the final hydroxylation and conversion of the vitamin D precursor, 25-hydroxyvitamin D, to the active form in the kidney. As kidney disease progresses the process is impaired and the resultant vitamin D deficiency leads to reduced intestinal calcium absorption and worsening hyperparathyroidism. Increases in FGF-23, which facilitate excretion of phosphorus, may also promote calcitriol deficiency.[21] Calcitriol deficiency is observed at all levels of GFR but is more prevalent in individuals with stage 3 CKD.[20] Many individuals with CKD are also deficient in 25-OH vitamin D. This may be the result of decreased dermal synthesis of vitamin D, decreased exposure to sunlight, and reduced dietary intake of vitamin D.[22] In patients with stage 3 or 4 CKD, 25-OH deficiency (levels of <30 ng/mL [<75 nmol/L]) are associated with increased PTH. Evaluation of 25-OH levels and supplementation with a vitamin D precursor (e.g., ergocalciferol or cholecalciferol) in patients with observed deficiencies are recommended for stages 3 and 4 CKD (opinion-based recommendation).[22]

The abnormalities of CKD-MBD lead to bone abnormalities and other associated consequences. The continuous high rate of production of PTH by the parathyroid glands promotes parathyroid hyperplasia. Nodular tissue demonstrates more rapid growth potential and appears to be associated with fewer vitamin D and calcium-sensing receptors, resulting in resistance to the effects of calcium and vitamin D therapy and subsequent development of ROD.[19] Bone abnormalities are found almost universally in ESRD patients and in the majority of those with stages 3–5 CKD.[18] The skeletal complications associated with the bone abnormalities include osteitis fibrosa cystica (high bone turnover disease), osteomalacia (low bone turnover disease), and adynamic bone disease. Osteitis fibrosa cystica is most common and is characterized by areas of peritrabecular fibrosis. Bone marrow fibrosis and decreased erythropoiesis are also consequences of severe osteitis fibrosa cystica. Osteomalacia was historically noted in hemodialysis patients with aluminum toxicity, a finding less common today due to the decreased use of aluminum-containing phosphate binders and changes in the processing of dialysate solutions to decrease aluminum absorption. Adynamic lesions are characterized by low amounts of fibrosis or osteoid tissue and low bone formation rates. The incidence of adynamic lesions has increased over the last 10 years and may be present in as many as 50% of dialysis patients.[23] Multiple risk factors for the development of this bone disease have been identified: high concentrations of dialysate calcium along with high doses of calcium-containing phosphate binders, aggressive management with vitamin D therapy, diabetes, aluminum toxicity, and advanced age.[23] Symptoms of ROD are often not evident until after significant skeletal damage has developed; consequently, prevention is the key to minimize the consequences of long-term complications. When symptoms such as bone pain and skeletal fractures occur, the disease is not easily amenable to treatment.

Of concern with CKD-MBD is the increased mortality associated with this complication. Secondary hyperparathyroidism (sHPT) as evidenced by PTH levels >495 pg/mL (>495 ng/L) in CKD patients is associated with increased morbidity and mortality and sudden death in hemodialysis patients.[24] Elevations of serum phosphorus, even within the upper limits of the normal range, have been associated with increased risk of cardiovascular events and/or mortality (all-cause or cardiovascular mortality) in patients with stages 3–5 CKD.[18,25] An elevated calcium times phosphorus product (Ca × P) is also associated with poor outcomes, including vascular calcification, cardiovascular disease, calciphylaxis, and death.[26] In two large, national, cross-sectional samples of hemodialysis patients who had received dialysis for at least 1 year, elevated serum phosphorus levels and Ca × P were associated with increased risk of death.[26,27] Patients with a Ca × P above 72 mg^2/dL^2 (5.8 $mmoL^2/L^2$) were found to have a 34% higher risk of death compared with patients with a Ca × P in the desired range of 43 to 52 mg^2/dL^2 (3.5 to 4.2 $mmoL^2/L^2$).[26] Calcium scores, as measured by electron-beam computed tomography, were significantly higher in hemodialysis patients than in patients without kidney disease who had proven coronary artery disease. Intake of calcium from calcium-based binders also appears to be a significant contributor to coronary artery calcification, even in young dialysis patients.[28] The incidence of calciphylaxis in patients with ESRD has increased over the last decade and has also been linked to elevated Ca × P product, although a direct cause and effect relationship has not been established.[29] These data underscore the need to consider all the consequences of elevated PTH, calcium, and phosphorus, not just their effects on bone.

CARDIOVASCULAR DISEASE

5 Patients with CKD are at increased risk of cardiovascular disease, independent of the etiology of their kidney disease. Mortality secondary to cardiovascular disease is 10 to 30 times greater in dialysis patients than in the general population.[30] Higher mortality has also been observed in individuals with stages 3–5 CKD. In a study with data from over 1,120,295 individuals from a Kaiser Permanente Renal Registry higher mortality and risk of cardiovascular events were reported for individuals with stage 3–5 CKD compared to those with an estimated GFR above 60 mL/min/1.73 m^2 (0.58 mL/s/m^2) (reference group).[31] The rate of death from any cause was 17% greater for individuals with stage 3 CKD and 600% greater in those with stage 5 CKD not requiring dialysis. The rate of cardiovascular events was also greater compared with the reference group, with an increase of 43% observed for those with stage 3 CKD and 343% for individuals with stage 5 CKD. A cardiovascular event was defined as hospitalization for coronary heart disease, heart failure, ischemic stroke, and peripheral arterial disease.

Although a clearly unique pathogenesis of cardiovascular disease specific to CKD has not been identified, it is known that manifestations of kidney disease are contributory.[30] Like diabetes CKD is considered a "coronary heart disease equivalent."[32] In addition to traditional cardiac risk factors such as hypertension and hyperlipidemia, diabetes, tobacco use, and physical inactivity, patients with kidney disease have other unique risk factors. Among these are hyperhomocysteinemia, elevated levels of C-reactive protein, increased oxidant stress, and hemodynamic overload.[3] Complications of CKD such as anemia and metabolic disorders (i.e., CKD-MBD) are also contributory. In particular, arterial vascular disease (e.g., atherosclerosis) and cardiomyopathy are the primary types of cardiovascular disorders present in the CKD population.[3,30] These disorders lead to development of ischemic heart disease and

its manifestations including myocardial infarction. As a predominant comorbidity, cardiovascular disorders and their sequelae are the leading cause of death in the ESRD population.[2,3]

Hypertension

The pathogenesis of hypertension in CKD is multifactorial, but for many, fluid retention is a major contributor. In addition to the other pathophysiologic mechanisms responsible for the development of hypertension, patients with ESRD may also have increased sympathetic activity, decreased activity of vasodilators such as nitric oxide, elevated levels of endothelin-1, chronic use of an ESA, hyperparathyroidism, and structural changes in the arteries (e.g., metastatic calcification) as contributing factors.[3] Patients with ESRD also display an abnormal diurnal blood pressure rhythm as evidenced by the fact that their blood pressure does not decrease during the nighttime hours.[3] It is unclear what causes this disturbance in the diurnal rhythm, but this "nondipping" phenomenon indicates sustained elevations in blood pressure are present over a prolonged period of time when compared with the general population.

Based on data from the 2009 USRDS, nine in ten Medicare CKD patients age 65 and older have a diagnosis of hypertension, an increase from 72% in 1995.[2] Hypertension induced by volume expansion and increased systemic vascular resistance increases myocardial work and contributes to development of left ventricular hypertrophy (LVH). A "U-shaped" relationship between blood pressure and mortality has been observed, such that higher mortality is associated with the highest and lowest levels of blood pressure.[3]

Hyperlipidemia

CKD with or without nephrotic syndrome is frequently accompanied by abnormalities in lipoprotein metabolism. It is well established that dyslipidemias cause atherosclerotic cardiovascular disease, and there are many compelling reasons to aggressively treat these disorders. A clear association between hypercholesterolemia, hypertriglyceridemia, or other lipoprotein changes in patients with CKD and cardiovascular disease has not been demonstrated in large prospective studies because individuals with kidney disease are usually excluded from these trials. It is likely that the same lipoprotein abnormalities that confer increased risk of cardiovascular disease in the general population would also be harmful to patients with kidney disease. This is supported by information from the Atherosclerosis Risk in Communities (ARIC) study.[33] In this study, the association between the severity of dyslipidemia and risk of future cardiovascular events evaluated over a 10.5-year follow-up period was similar to that in patients who had normal kidney function.[33]

A low or declining serum cholesterol in patients with ESRD is also associated with higher mortality, a paradoxical effect.[3] These findings beg the question of whether aggressive lipid lowering is warranted in this population. Further analysis, however, shows that low cholesterol levels were observed in conjunction with inflammation and malnutrition, factors that increase mortality. In the absence of these confounding factors, it is the higher cholesterol levels, not the lower levels, that were associated with increased mortality.

The lipid panel generally observed in patients with CKD without nephrotic syndrome is a normal total and low-density lipoprotein (LDL) cholesterol, low high-density lipoprotein (HDL), and high triglycerides (plasma concentrations >200 mg/dL [>2.26 mmol/L]).[34] Although the concentrations of LDL are not uniformly increased in patients with kidney disease, these patients appear to produce small, dense LDL particles that are more susceptible to oxidation and more atherogenic than larger LDL subfractions. Other lipoprotein abnormalities include changes in apoprotein content of lipoprotein molecules and increased very-low-density and intermediate-density lipoproteins. For patients with CKD and a urinary protein excretion greater than 3 g/day (as in nephrotic syndrome), the major lipid abnormalities are elevation of plasma total and LDL cholesterol, with or without low HDL cholesterol (<35 mg/dL [<0.91 mmol/L]) and elevated triglycerides. Treatment of proteinuria resolves the hyperlipidemia in most patients with nephrotic syndrome.

CLINICAL PRESENTATION

Damage to the kidney has detrimental consequences for many other organ systems, particularly once patients develop ESRD. The subjective and objective findings of CKD that may be present in an individual are dependent on the severity of disease (i.e., stage of CKD). At the time of referral to a nephrologist patients may present with some, but rarely all, of the signs and symptoms associated with uremia and secondary complications of CKD, unless they are in stage 4 or 5 CKD. It is apparent that management of CKD requires treatment of multiple secondary complications. Unfortunately many CKD patients are not diagnosed with the disease until they reach stage 5 CKD and are at or near the point of requiring renal replacement therapy. This problem has prompted automated reporting of the estimated glomerular filtration rate (eGFR) by clinical labs as determined by the MDRD equation for the purpose of identifying individuals with CKD earlier (see Chaps. 50 and 52). Clinicians must understand how to interpret the eGFR appropriately to stage individuals with kidney disease and determine the best options to delay progression and manage the associated complications.

CLINICAL PRESENTATION OF STAGE 4 OR 5 CHRONIC KIDNEY DISEASE

Symptoms

- Uremic symptoms (fatigue, weakness, shortness of breath, mental confusion, nausea and vomiting, bleeding, and loss of appetite), as well as itching, cold intolerance, weight gain, and peripheral neuropathies are common in patients with stage 5 disease.

Signs

- Edema, changes in urine output (volume and consistency), "foaming" of urine (indicative of proteinuria), and abdominal distension.

Laboratory Tests[a]

- *Decreased*: creatinine clearance, bicarbonate (metabolic acidosis), hemoglobin/hematocrit (anemia), iron stores (iron deficiency), vitamin D levels, albumin (malnutrition), glucose (may result from decreased degradation of insulin with impaired kidney function or poor oral intake), calcium (in early stages of CKD), HDL.
- *Increased*: serum creatinine, blood urea nitrogen, potassium, phosphorus, PTH, blood pressure (hypertension is a common cause and result of CKD), glucose (uncontrolled diabetes is a cause of CKD), low-density lipoprotein and triglycerides, calcium (in ESRD)
- *Other*: May be hemoccult-positive if GI bleeding occurs secondary to uremia.

Other Diagnostic Tests

- Left ventricular hypertrophy may be observed, as well as increased homocysteine levels and increased C-reactive protein.

TABLE 53-2 Target Hb and Iron Indices for Anemia Management in Chronic Kidney Disease[53]

Parameter	ND-CKD and PD-CKD	HD-CKD
Hb	11–12 g/dL (110–120 g/L; 6.83–7.45 mmol/L)	11–12 g/dL (110–120 g/L; 6.83–7.45 mmol/L
TSat	>20% (>0.20)	>20% (>0.20)
CHr	–	>29 pg/cell
Serum ferritin[a]	>100 ng/mL (>100 µg/L)	>200 ng/mL (>200 µg/L)

ND-CKD, nondialysis CKD patients; PD-CKD, peritoneal dialysis patients; HD-CKD, hemodialysis patients;
CHr, content of hemoglobin in reticulocytes; CKD, chronic kidney disease; Hb, hemoglobin; TSat, transferrin saturation.
[a]Serum ferritin is an acute phase reactant–use clinical judgment when above 500 ng/mL (500 µg/L).

ANEMIA OF CHRONIC KIDNEY DISEASE

Since many individuals with anemia of CKD are asymptomatic upon presentation, laboratory evaluation is commonly the initial approach to diagnosing anemia of CKD. According to the KDOQI guidelines for anemia management in CKD the hemoglobin (Hb) should be measured in all individuals with CKD regardless of stage.[35] The diagnosis of anemia is made and further workup of anemia is required when the Hb is less than 13.5 g/dL (135 g/L; 8.38 mmol/L) for adult males and less than 12 g/dL (120 g/L; 7.45 mmol/L) for adult females. Iron deficiency is the primary cause of resistance to treatment of anemia with ESAs; therefore, assessment of the iron status is required. The iron indices transferrin saturation (TSat) and serum ferritin provide information on iron immediately available for use in the bone marrow for red blood cell production (TSat) and storage iron (serum ferritin). The TSat is calculated as ([serum iron/TIBC] × 100), where TIBC is the total iron-binding capacity. If the TSat and serum ferritin values are below the desired threshold (Table 53–2), iron supplementation is warranted.

Additional workup includes evaluation for the presence of other potential causes of anemia such as blood loss, deficiencies in vitamin B_{12} or folate, or other disease states that contribute to anemia, including human immunodeficiency virus infection and malignancies. Red blood cell indices (mean corpuscular hemoglobin, mean corpuscular volume, mean corpuscular hemoglobin concentration), white blood cell count, differential and platelet count, and absolute reticulocyte count should also be assessed. A stool guaiac test should be performed to rule out GI bleeding.

Iron supplementation is required by most CKD patients receiving an ESA because of the increased iron demand that results from stimulation of red blood cell production. As CKD worsens, a progressive decline in Hb despite ESA therapy may be observed. Consequently, regular evaluation of Hb and iron status is warranted to ensure the desired outcomes are met and to make necessary dose adjustments in ESAs and iron therapy. Iron supplementation may also be required in individuals with anemia who have *iron restricted erythropoiesis*. In this condition the individual with anemia may have a TSat below goal (less than 20% [0.20]); however, the serum ferritin may be at goal (e.g., above 100–200 ng/mL [100–200 µg/L]) or even elevated. It has been shown that anemic hemodialysis patients with a TSat less than 25% (0.25) and serum ferritin between 200 and 1200 ng/mL (200–1200 µg/L) had an improved response to ESAs when they also received a 1 g course of IV iron.[36]

Signs and symptoms of anemia of CKD include, but are not limited to, fatigue, shortness of breath, cold intolerance, chest pain, tingling in the extremities, tachycardia, headaches, and general malaise. The effects of anemia and decreased oxygen delivery on other comorbid conditions, including LVH, have been considered given the burden of cardiovascular complications in this population. Despite associations of worsening anemia with development of LVH, there are no prospective studies demonstrating that early and aggressive treatment improves cardiovascular end points or LVH in the CKD population. Improvements in quality of life have been observed with increased Hb, but such improvements must be weighed against reported risks of more aggressive anemia management to achieve higher Hb levels in the CKD population.[37]

CKD-MINERAL AND BONE DISORDER (CKD-MBD) AND RENAL OSTEODYSTROPHY

The K/DOQI clinical practice guidelines for bone metabolism and disease have been available since 2003 and provide recommendations for the workup and treatment of CKD-MBD.[22] In 2009 the KDIGO clinical practice guidelines for CKD-MDB were published.[18] Recommendations from both the K/DOQI and KDIGO are presented here. It should be noted that many of the recommendations are based on opinion or limited evidence given the lack of randomized, controlled studies to evaluate outcomes of treating the biochemical abnormalities to specific targets.

The biochemical abnormalities of CKD-MBD should be evaluated in patients with stage 3 CKD and include an evaluation of serum phosphorus, calcium, Ca × P product, and PTH. The recommended frequencies of monitoring calcium, phosphorus, and PTH by CKD stage based on the K/DOQI and KDIGO guidelines are shown in Table 53–3.[18,22] The KDIGO guidelines also recommend monitoring bone-specific alkaline phosphatase annually in stage 4 and 5 CKD patients. The frequency of monitoring these parameters may increase once a diagnosis of CKD-MDB is made and further information is needed to assess the patient's response to treatment and to guide decisions about changes in therapy.

Clinicians involved in the care of patients with CKD should know which PTH assays are available in their facilities. PTH is secreted from the parathyroid gland as intact PTH, an 84-amino-acid peptide chain (1–84 PTH) that is biologically active, and as smaller carboxy-terminal PTH fragments.[38] Circulating levels of these fragments (e.g., 7–84 PTH) may increase substantially in patients with CKD and actively antagonize the effects to 1–84 PTH. The available immunoradiometric assays, known as second-generation assays,

TABLE 53-3 Recommended Frequency of Monitoring Calcium, Phosphorus, PTH , and 25 OHD by Stage of CKD (K/DOQI and KDIGO Guidelines)[18,22]

	Calcium and Phosphorus		PTH		25-Hydroxyvitamin D	
CKD Stage	K/DOQI	KDIGO	K/DOQI	KDIGO	K/DOQI	KDIGO
3	Annually	Every 6–12 months	Annually	Baseline, then based on CKD progression	If PTH above target	Baseline level; correct deficiencies as in general population
4	Every 3 months	Every 3–6 months	Every 3 months	Every 6–12 months		
5	Monthly	Every 1–3 months	Every 3 months	Every 3–6 months	Not measured	

KDIGO, Kidney Disease: Improving Global Outcomes; K/DOQI, Kidney Disease Outcomes Quality Initiative; PTH, parathyroid hormone.

TABLE 53-4 Guidelines for Calcium, Phosphorus, Calcium Phosphorus Product, and Intact Parathyroid Hormone[a,18,22]

	Chronic Kidney Disease		
Parameter	**Stage 3**	**Stage 4**	**Stage 5**
Corrected calcium	"Normal"	"Normal"	8.4–9.5 mg/dL[b] (2.10–2.38 mmol/L)
Phosphorus	2.7–4.6 mg/dL (0.87–1.49 mmol/L)	2.7–4.6 mg/dL (0.87–1.49 mmol/L)	3.5–5.5 mg/dL (1.13–1.78 mmol/L)
Ca × P	<55 mg^2/dL^2 [4.4 $mmol^2/L^2$]	<55 mg^2/dL^2 (4.4 $mmol^2/L^2$)	<55 mg^2/dL^2 (4.4 $mmol^2/L^2$)
Intact parathyroid hormone	35–70 pg/mL (35–70 ng/L)	70–110 pg/mL (70–110 ng/L)	150–300 pg/mL (150–300 ng/L)

[a] Differences with Kidney Disease: Improving Global Outcomes (KDIGO) described in text (see CKD-MBD Desired Outcome section).
[b] Recommend normal range for laboratory used, but keeping target at lower end of range.

measure not only the intact PTH molecule but also fragments, which may lead to overestimation of biologically active PTH. A correction factor for these fragments cannot be established since commercially available assays measure different types and amounts of these fragments and give inconsistent results. For this reason KDIGO did not specify a particular PTH target, but rather advocated looking at trends in serum PTH to make treatment decisions. For the dialysis population KDIGO recommends a general PTH range of two to nine times the upper limit of the normal range for the assay.[18] This differs from the K/DOQI guidelines which recommend specific ranges for each stage of CKD (Table 53–4). The risks associated with sustained elevations in PTH that would be permitted by following the KDIGO guidelines have raised concern and, at present, the K/DOQI recommendations continue to serve as the basis for treating CKD-MBD.

In addition to monitoring for biochemical abnormalities that define CKD-MBD and are associated with negative outcomes, evaluation of bone architecture is also necessary in some cases. Individuals with stages 3–5 CKD and metabolic abnormalities of CKD-MBD (e.g., abnormal phosphorus, calcium, PTH, and vitamin D) with bone involvement are said to have renal osteodystrophy. The gold standard test for diagnosing renal osteodystrophy is bone biopsy for histologic analysis; however, this is an invasive test that is not easily performed. Both K/DOQI and KDIGO guidelines recommend bone biopsy only in patients in whom the etiology of symptoms is not clear or in individuals with more unique biochemical abnormalities.[18,22] This includes patients experiencing unexplained fractures, persistent hypercalcemia, and possible aluminum toxicity.[22] If aluminum concentrations are elevated (60 to 200 µg/L [2.2 to 7.4 µmol/L]) a deferoxamine test should be done. KDIGO also suggests a bone biopsy be considered in CKD patients prior to beginning treatment with bisphosphonates since adynamic bone disease is a contraindication to the use of these agents. Bone biopsy findings are described on the basis of turnover rate, mineralization, and volume. High bone turnover disease, or *osteitis fibrosa*, is a common pattern observed with renal osteodystrophy, although individuals may also have low bone turnover disease. Bone mineral density testing is not generally recommended in patients with advanced CKD since this test has not been shown to predict fracture risk and does not indicate the type of renal osteodystrophy.[18]

Abnormalities in mineral metabolism are highly associated with vascular and soft-tissue calcifications, known risk factors for mortality; therefore, diagnostic testing for calcifications should be considered in the evaluation for CKD-MBD. Electron-beam computed tomography (EBCT) is a noninvasive and sensitive method available for detecting cardiovascular calcifications and has been used clinically and in studies in the CKD population. Other methods advocated include lateral abdominal radiographs to detect vascular calcification and echocardiogram to detect valvular calcification. KDIGO suggests these tests are reasonable alternatives to EBCT based on the sensitivity to detect calcifications and lower cost.[18]

METABOLIC ACIDOSIS

Metabolic acidosis generally does not occur until stage 4 CKD. The complete evaluation of acid–base status requires measurement of serum electrolytes and arterial blood gases when acidosis is suspected. A complete medical history and review of medications is necessary to determine whether there are other potential causes of acid–base disturbances (e.g., diabetic ketoacidosis, ingestion of toxins, or GI disorders). The anion gap, indicating the differences in unmeasured cations and anions, should also be calculated (see Chap. 61). An elevated anion gap (>17 mEq/L [>17 mmol/L]) is often present in patients with stage 4 or 5 CKD because of the accumulation of organic anions, phosphates, and sulfates. Treatment of metabolic acidosis in patients with CKD generally includes administration of bicarbonate to correct acidemia with the time course for correction depending on the severity of the acidosis. Asymptomatic patients with mild acidosis (bicarbonate of 12 to 20 mEq/L [12 to 20 mmol/L; pH of 7.2 to 7.4) generally do not require emergent therapy, and gradual correction with oral bicarbonate administration over days to weeks is appropriate.

CARDIOVASCULAR DISEASE

Individuals with CKD are at increased risk for CVD; thus screening for the presence of cardiovascular risk factors is a high priority in this population. Individuals with stage 4 CKD should be assessed for cardiovascular risk factors and considered in the highest risk group for cardiovascular events. The risk of developing congestive heart failure increases in both young and elderly CKD patients.[2] Modifiable cardiovascular risk factors in patients with CKD are hypertension, diabetes mellitus, hyperlipidemia, and smoking.[33] The K/DOQI guidelines for stage 5 dialysis patients recommend that all patients starting dialysis be assessed for cardiovascular disease (including coronary artery disease, cardiomyopathy, valvular heart disease, cerebrovascular disease, and peripheral vascular disease) and be screened for traditional (e.g., hypertension and hyperlipidemia) and nontraditional cardiovascular risk factors.[3]

Hypertension

As in the general population patients with CKD may not have symptoms of elevated blood pressure; therefore, blood pressure monitoring is essential. Edema and other indications of volume expansion may be observed in individuals with hypertension as a result of volume overload. Patients with stages 4 and 5 CKD should have their blood pressure evaluated at every clinic visit and at home, if feasible. Patients with ESRD should have their blood pressure monitored at every scheduled clinic visit (or hemodialysis session), and they should also be encouraged to learn how to monitor their blood pressure while at home. Patients who have required extensive surgeries in both arms to establish vascular accesses should have blood pressure measured in the thighs or legs. Blood pressure should be measured with an appropriate-size cuff prior to insertion of the needles for hemodialysis.

Blood pressure monitoring performed in the clinical setting has been shown to both overestimate and underestimate true blood pressure in CKD patients.[39,40] Ambulatory blood pressure monitoring (ABPM) is recommended in individuals with CKD to better determine variations in blood pressure throughout the day and to detect the "nondipping phenomenon" (loss of the protective decline in blood pressure that occurs during sleep) that is more common in the CKD population. ABPM has also been shown to better correlate with end organ damage (e.g., proteinuria) than blood pressure readings measured in the clinical setting. ABPM is also recommended for dialysis patients since both pre- and postdialysis blood pressures are poor indicators of interdialytic blood pressure.[39]

Hyperlipidemia

A complete fasting lipid profile including total cholesterol, LDL, HDL, and triglycerides should be done in all CKD patients. Lipoprotein levels may be influenced by several factors, including GFR and proteinuria. It is recommended that CKD patients have their lipid profile assessed more frequently than the general population to identify abnormalities and treat them early. In patients on hemodialysis the lipid profile should be done prior to dialysis or on nondialysis days.[41] Patients should also be evaluated for other conditions that are known to cause dyslipidemias (e.g., liver disease).

TREATMENT

Chronic Kidney Disease

Once a patient is diagnosed with CKD, implementation of therapy to address the primary cause (e.g., diabetes, hypertension, or glomerulonephritis) and to delay progression is a priority. The key concepts involved in the management of disease progression are discussed in detail in Chapter 52. When patients reach stage 4 CKD, progression to ESRD is almost inevitable, although the process may be delayed if appropriate therapy is initiated. It is during stage 4 CKD that planning for renal replacement therapy (hemodialysis or peritoneal dialysis) should begin, including patient education about dialysis modalities and options for transplantation (see Chap. 54 and 98).

6 Individuals with CKD should be evaluated for secondary complications (e.g., anemia and CKD-MBD) and comorbid conditions and receive treatment for these complications prior to development of ESRD. Historically, the common complications of anemia and CKD-MBD have not been diagnosed or appropriately managed in the earlier stages of CKD.[2] Late referral to a nephrologist may in part account for this poor management; however, even in ideal clinical environments such as nephrology clinics, these secondary complications may be overlooked. There are opportunities for other health care professionals to make recommendations for appropriate workup and management of CKD and its associated complications.

DESIRED OUTCOME

The overall goal of therapy in individuals with stage 2, 3, and the early phase of stage 4 CKD is to delay or prevent progression of the disease and the associated comorbidities. Patients who reach CKD stage 4 almost inevitably experience progression to ESRD and thus at some time in the near future will require dialysis or transplantation to sustain life. The primary goal is to sustain a good quality of life and prevent adverse outcomes by aggressively managing complications of advanced CKD.

GENERAL APPROACH TO PATIENT CARE

7 Management of the existent complications and consequences of CKD should be based on the most current consensus guidelines and the best clinical practices such as those developed by the NKF-K/DOQI, KDIGO, Cochrane Renal group, and other relevant professional associations. The K/DOQI guidelines and recommendations were developed based on evidence, when available, or the opinion of an expert group of individuals when sufficient evidence was lacking. Recommendations based primarily on opinion have been subject to some criticism. With this in mind, the K/DOQI guidelines should not replace clinical judgment, but should provide a basis upon which treatment decisions can be made in the context of both evidence and opinion. The secondary complications that are addressed in the currently available clinical practice guidelines include anemia of CKD, bone metabolism and disease, cardiovascular disease in dialysis patients, dyslipidemias, hypertension, and nutrition.

8 Appropriate management of secondary complications of CKD ideally involves a multidisciplinary approach to address the nonpharmacologic and pharmacologic interventions, dietary education, and social/financial concerns. The typical team includes physicians (nephrologists), nurses, dietitians, and social workers in outpatient dialysis facilities. In some outpatient dialysis centers pharmacists are also active members of the care team, although this is more common in dialysis units associated with healthcare institutions.

Reducing the incidence and risk of drug-related problems (DRPs) is one of the primary goals in caring for the CKD patient. ESRD patients are prescribed an average of 8 to 10 medications, which increases the potential of DRPs.[42] This risk is further compounded by the fact that many patients see practitioners outside of the dialysis unit and receive prescriptions from these providers in addition to the medications they require during dialysis. Medication reconciliation is essential to reduce the risk of DRPs and requires that pharmacists and other practitioners consult with the dialysis facilities to get a complete medication history. Pharmacists in the community must be prepared to provide medication therapy management (MTM) for individuals with CKD since this population receives medications and care in the community settings. Frequent medication reviews are paramount to reduce DRPs and patient exposure of these patients to nephrotoxic agents (see Chap. 54). Drug-dosing guidelines based on the degree of kidney function should be followed, and a complete medication history of prescription and nonprescription medications, as well as herbals and nutritional supplements, should be obtained and routinely updated. Chronic use of nonsteroidal antiinflammatory drugs and cyclooxygenase-2 inhibitors should be avoided when possible. Patients should be instructed on all brand and generic names of these classes of medications to reduce the risk of exposure. Appropriate measures should also be taken for hospitalized patients to decrease the risk of nephrotoxicity from radiocontrast agents (for procedures requiring such dyes), and antibiotics such as aminoglycosides, as well as from nonsteroidal antiinflammatory drugs and angiotensin-converting enzyme inhibitors (ACEIs) (see Chaps. 51 and 55).

Continued patient education, initiated prior to development of ESRD, is essential to help patients become active participants in their own care and to become knowledgeable about medications which they often require on a chronic basis. Pharmacists involved with the dialysis population have identified many specific drug-related problems (e.g., inappropriate dose or indication for a medication, adverse drug reactions) that commonly occur in the ESRD population and have demonstrated that clinical pharmacy services reduce such problems and improve patient quality of life.[42]

FLUID AND ELECTROLYTE ABNORMALITIES

Maintenance of fluid volume, osmolarity, electrolyte balance, and acid–base status are all regulated in large part by the kidney and their homeostasis is altered in patients with impaired kidney function. A comprehensive discussion of fluid and electrolyte disorders and treatment options is presented in Chapters 58–60. The unique aspects of treatment of sodium, water, and potassium disorders in stage 4 CKD and dialysis patients are highlighted here.

Desired Outcomes

Sodium and Water Homeostasis The goal in the individual with CKD is to maintain sodium and water balance as indicated by serum sodium concentrations in the normal range (i.e., 135 to 145 mEq/L [135 to 145 mmol/L]) and a euvolemic state. By achieving these goals, the risk of developing or worsening hypertension secondary to volume overload is reduced. Achievement of these goals is also warranted to prevent complications in individuals with congestive heart failure or other conditions that may be affected by volume status.

Potassium Homeostasis The focus is on prevention of hyperkalemia and its acute adverse consequences, particularly cardiac effects, while maintaining potassium concentrations of approximately 4 to 5.5 mEq/L (4 to 5.5 mmol/L). This is often achieved through dietary restriction of potassium, minimizing exposure to medications that may increase serum potassium, and use of sodium–potassium exchange resins when indicated. If hyperkalemia develops, management options are based on the rapidity and degree to which potassium is elevated (see Chap. 60).

Nonpharmacologic Therapy

Sodium and Water Homeostasis The ability of the kidney to adjust to abrupt changes in sodium intake is greatly diminished in patients with severe CKD. Sodium restriction beyond a no-added-salt diet should generally not be recommended. The kidney maintains the ability to lower urinary sodium content to essentially zero, but this can only be accomplished by very gradual sodium restriction over a period of several days. Hospitalized patients with CKD should not routinely be sodium restricted because they have adapted to their outpatient intake. Negative sodium balance and its resultant volume contraction can cause decreased kidney perfusion and an acute decline in GFR.

Fluid restriction is generally unnecessary for CKD patients not requiring dialysis provided sodium intake is controlled. An intact thirst mechanism maintains total-body water and effective plasma osmolality near normal. Large amounts of free water administered orally or as IV fluid may induce hyponatremia and volume overload. Sodium retention and volume expansion also contribute to hypertension in many patients with severe CKD, and diuretic therapy may be necessary to control edema or blood pressure. Saline-containing IV solutions should also be used cautiously in patients with CKD because the kidney's ability to excrete a salt load is impaired and the kidneys are prone to volume overload. Sodium restriction (e.g., less than 2 g per day) is warranted in the ESRD population to help control volume status.

Potassium Homeostasis Hyperkalemia is more common in patients with stage 5 CKD and in those who require dialysis. The majority of patients can be managed with a dietary potassium restriction of 50 to 80 mEq/day (50 to 80 mmol/day) and a reduction in dialysate potassium concentrations (see Chap. 54). Hyperkalemia is less common in the peritoneal dialysis population because of the more extensive removal of potassium by the peritoneal dialysis procedure and therefore, these patients are often allowed more liberal dietary potassium intake.

Pharmacologic Therapy

Sodium and Water Homeostasis Diuretic therapy is often necessary to prevent edema and the associated symptoms from volume overload. Loop diuretics increase urine volume and renal sodium excretion even in individuals with stage 4 CKD. Diuretic resistance can occur and requires use of higher doses of loop diuretics. In these situations a combination of a loop diuretic with the thiazide diuretic, metolazone, can substantially increase excretion of sodium and water (see Chap. 58). When a patient develops ESRD diuretics become ineffective as residual kidney function is lost and dialysis becomes necessary to control volume status.

Potassium Homeostasis The definitive treatment of severe hyperkalemia for a dialysis-dependent ESRD patient is hemodialysis. In reality, there is often a delay between diagnosis of hyperkalemia and institution of dialysis, which necessitates the use of other temporizing measures, such as IV calcium gluconate, insulin and glucose, nebulized β_2-adrenergic agonists (albuterol), and sodium polystyrene sulfonate (see Chap. 60). Unfortunately, shifting potassium into the intracellular fluid compartment with insulin and glucose or with albuterol makes removal of potassium via dialysis more difficult. Multiple dialysis sessions may be necessary following potassium redistribution to the extracellular space. Sodium polystyrene sulfonate, a potassium–sodium exchange resin, can be given orally in doses of 30 to 60 g to increase potassium excretion via the ileum and colon. Sodium bicarbonate therapy is no longer advocated in the treatment of ESRD hyperkalemia unless severe metabolic acidosis is also present because the potassium-lowering effect is unreliable. Loop diuretics, a standard pharmacologic treatment option for hyperkalemia, are ineffective in patients with ESRD.

Each patient's medications should routinely be reviewed to identify those that increase serum potassium. This includes potassium-sparing diuretics, β-blockers, which interfere with the extrarenal translocation of potassium into cells, and ACEIs, which may cause hyperkalemia by reducing aldosterone production. Polycitra, used for the treatment of metabolic acidosis, contains potassium citrate and should not be prescribed for patients with severe CKD. The contribution of dialysis modalities to potassium homeostasis in patients with ESRD must also be considered (see Chap. 54). Constipation in patients with CKD can interfere with colonic potassium excretion; therefore a good bowel regimen is also important.

Evaluation of Therapeutic Outcomes

Monitoring of volume status and serum electrolyte levels should be done at each clinic visit in patients with stages 4 and 5 CKD. This should include an evaluation of signs and symptoms of extracellular fluid volume expansion (e.g., pitting edema, rales, ascites, shortness of breath, and increased weight) and consequences of volume overload (e.g., hypertension, pulmonary edema) and hyperkalemia (e.g., arrhythmias). Blood pressure monitoring in the clinic setting and at home, if feasible, is recommended to detect onset or worsening of hypertension and to monitor the efficacy of the antihypertensive regimens. As kidney disease progresses dietary intervention and diuretic therapy will likely become necessary.

Serum electrolytes are generally measured monthly in the dialysis population. Additional monitoring in the hemodialysis population includes assessment of the predialysis weight compared to a patient's dry weight (the target weight following hemodialysis at which the patient is hemodynamically stable). The greater the difference in weight, the more volume an individual has accumulated since the last hemodialysis session. While the hemodialysis prescription can be altered acutely to remove more volume by

increasing ultrafiltration (see Chap. 54), a patient consistently gaining excessive weight between dialysis sessions will require counseling on restriction of sodium and water.

ANEMIA OF CHRONIC KIDNEY DISEASE

Desired Outcome

The desired outcomes of anemia management are to increase oxygen-carrying capacity, decrease signs and symptoms of anemia, improve the patient's quality of life, and decrease the need for blood transfusions. Achievement of these goals requires a combination of an ESA and iron supplementation to promote and maintain erythropoiesis. Hemoglobin (Hb) is the preferred monitoring parameter for red blood cell production because, unlike Hct, its concentration is not affected by blood storage conditions and instrumentation used for analysis. Table 53–2 lists the target Hb and iron indices for those stage 5 CKD patients who are dialysis dependent as well as those not yet receiving dialysis.

Target Hemoglobin The recommended target Hb in all stage 5 CKD patients receiving ESAs is 11 to 12 g/dL (110–120 g/L; 6.83–7.45 mmol/L).[17] This target range is clearly below the "normal Hb" range and has been a topic of much debate for several years. Observational studies and USRDS data have shown decreased hospitalizations, lower mortality, and improved quality of life with Hb levels above 11 g/dL (110 g/L; 6.83 mmol/L).[43–45] "Normalization" of Hb to levels above 12 g/dL (120 g/L; 7.45 mmol/L) with ESA therapy, however, has resulted in increased risk of mortality and cardiovascular events compared with patients maintained in the 11 to 12 g/dL (110–120 g/L; 6.83–7.45 mmol/L) range. These conclusions were based on results reported in 2006 from clinical trials (CHOIR and CREATE trials) that included individuals with early stage CKD and from previous data reported in the hemodialysis population (Normal Hematocrit Cardiac Trial, NHCT).[15,16,46] A summary of these key trials is shown in Table 53–5. An increased risk of all-cause mortality with ESA treatment was also reported in a meta-analysis of nine randomized, controlled trials that included over 5,100 CKD patients treated to Hb targets in the range of 12 to

TABLE 53-5 Trials Evaluating ESAs and Target Hb/Hct

Study	Study Population and End Points	ESA	Target Hb or Hct	Results	Comments
Normal Hematocrit Cardiac Trial (NHCT)[16,131]	1,265 ESRD patients with CHF or ischemic heart disease on hemodialysis *Primary end points*: Length of time to death or first MI	Epoetin alfa	Low Hct 32% (0.32) (n = 631) "Normal" Hct 42% (0.42) (n = 634)	Study was stopped before completion when the group randomized to a higher Hct target showed a trend toward higher mortality and nonfatal MI [relative risk (RR) 1.28, 95% CI 0.92–1.78]	Higher Hct target in the hemodialysis population with cardiovascular disease was not supported.
Correction of Hb and Outcomes in Renal Insufficiency (CHOIR)[15]	1432 Stage 3-4 CKD patients *Primary end points*: Composite of death, MI, hospitalization for congestive heart failure, and stroke	Epoetin alfa	Low Hb 11.3 g/dL (113 g/L; 7.01 mmol/L) (n = 717) High Hb 13.5 g/dL (135 g/L; 8.38 mmol/L) (n = 715)	Study stopped before completion because of a higher risk of the composite of death, stroke, MI, and hospitalization for CHF in the group randomized to higher Hb target [hazard ratio1.34; 95% CI 1.03–1.74]	Mean Hb for high Hb group was 12.6 g/dL (126 g/L; 7.82 mmol/L); mean Hb for low Hb group was 11.3 g/dL (113 g/L; 7.01 mmol/L). Those who reached the target Hb in the higher Hb group received larger doses of epoetin alfa (10,694 Units) compared to those who achieved the target Hb in the lower Hb group (6,057 Units).
Cardiovascular Risk Reduction by Early Anemia Treatment with Epoetin Beta (CREATE)[46]	603 CKD patients (primarily Stage 4) *Primary end point*: Composite cardiovascular events	Epoetin beta	Partial anemia correction group: Hb 10.5–11.5 g/dL (105–115 g/L; 6.52–7.14 mmol/L) (n = 302) Complete anemia correction group: Hb 13.0–15.0 g/dL (130–150 g/L; 8.07–9.31 mmol/L) (n = 301)	No significant difference in the risk of a first cardiovascular event between the complete correction and partial correction groups (hazard ratio: 0.78; 95% CI: 0.53 to 1.14; P = 0.20)	More frequent dialysis initiation (42 vs 37%, P = 0.03) and hypertension (30 vs 20%, P = 0.005) in the group randomized to a higher Hb target
Trial to Reduce Cardiovascular Events with Aranesp Therapy (TREAT)[52]	4,038 stage 3–4 CKD pts with type 2 DM *Primary end points*: Composite outcomes of death or a cardiovascular event and of death or ESRD	Darbepoetin alfa or placebo	13 g/dL (130 g/L; 8.07 mmol/L) for darbepoetin group (n = 2,012) Placebo group received darbepoetin as rescue therapy if Hb <9 g/dL (<90 g/L; 5.59 mmol/L) (n = 2,026)	No evidence of benefit with darbepoetin alfa and a trend toward harm: Death or a cardiovascular event (hazard ratio for darbepoetin vs. placebo, 1.05; 95% CI, 0.94 to 1.17; P = 0.41). Death or ESRD (hazard ratio, 1.06; 95% CI, 0.95 to 1.19; P = 0.29). Fatal or nonfatal stroke (hazard ratio, 1.92; 95% CI, 1.38–2.68; P <0.001).	Median Hb achieved was 12.5 g/dL (125 g/L; 7.76 mmol/L) in darbepoetin group and 10.6 g/dL (106 g/L; 6.58 mmol/L) in placebo group. Patients with a history of cancer in the higher Hb group also had a higher risk of death.

CHF, congestive heart failure; DM, diabetes mellitus; ESA, erythropoietic-stimulating agent; ESRD, end-stage renal disease.

16 g/dL (120–160 g/L; 7.45–9.93 mmol/L).[47] There was also a higher risk of dialysis access thrombosis and uncontrolled blood pressure in the higher Hb group. Following the release of CHOIR and CREATE the Centers for Medicare and Medicaid Services (CMS), which pays dialysis facilities for a significant portion of services, changed the reimbursement structure for ESAs to reduce payment by 50% if the Hb remained above 13 g/dL (130 g/L; 8.07 mmol/L) for 3 months or greater to promote more conservative and less costly use of ESAs.

The association of poor outcomes with dose of ESA used in the aforementioned studies has also raised concern. Subsequent analysis of the CHOIR study showed that high-dose ESA use was associated with greater risk of death.[48] Those individuals able to achieve the target Hb in the CHOIR study did not have worse outcomes. Further analysis of the NHCT data also showed a reduction in mortality by 60% for those individuals who responded to epoetin therapy compared with nonresponders.[49] Higher mortality with higher ESA dose has also been reported in other observational studies.[50] Such findings have led to discussion of whether hyporesponsiveness to ESAs due to other conditions such as inflammation may explain the higher event rates in this group of individuals. The overall negative cardiovascular outcomes observed with higher Hb targets in the randomized trials has prompted much discussion about the potential causes, including not only ESA dose and Hb target but also the rate of rise in Hb and the variability in Hb over time (e.g., degree of fluctuation in Hb).[51]

Additional discussion on this topic has also been stimulated by the initial results from the Trial to Reduce Cardiovascular Events with Aranesp Therapy (TREAT), a trial initiated prior to the release of data from the CHOIR and CREATE studies (Table 53–5).[52] Despite the association between anemia and reduction in hospitalization and cardiovascular events that prompted many to expect positive outcomes from this study, individuals treated to the higher Hb target did not have a reduction in the defined primary end points compared with the lower Hb group. In addition, there was also an almost twofold increase in the risk of stroke (5% in the treatment group vs 2.6 % in the placebo group). Those patients with a history of cancer in the higher Hb group also had a higher risk of death, a finding that requires additional investigation. These findings further support the recommendation of adhering to the recommendations in the labeling of not exceeding a Hb of 12 g/dL (120 g/L; 7.45 mmol/L).

CLINICAL CONTROVERSY

The higher risk of mortality and cardiovascular events in CKD patients treated to achieve a higher Hb with an ESA has led to an update in targets for Hb. There is a discrepancy, however, in the FDA target Hb (10–12 g/dL [100–120 g/L; 6.21–7.45 mmol/L]) stated in the labeling for ESAs and the K/DOQI target Hb (11–12 g/dL [110–120 g/L; 6.83–7.45 mmol/L]), not to exceed 13 g/dL (130 g/L; 8.07 mmol/L). There are also practitioners who advocate that for patients without specific cardiovascular risk factors (e.g., atherosclerosis) a Hb of 12–13 g/dL (120–130 g/L; 7.45–8.07 mmol/L) achieved with low-dose ESA is reasonable. Healthcare providers must weigh the risks and benefits of ESA use in individual patients and consider the reimbursement structure for ESAs and iron in the practice environment when making decisions about anemia management.

Iron Status Iron indices that should be monitored include the TSat, an indicator of iron immediately available for delivery to the bone marrow, and serum ferritin, an indirect measure of storage iron. The content of hemoglobin in reticulocytes (CHr) is also recommended as a parameter to assess iron status in hemodialysis patients, although it is not as commonly used in clinical practice as the TSat (see Table 53–2). Transferrin is the carrier protein for iron and, as a protein, may be affected by nutritional status. Serum ferritin is an acute-phase reactant, meaning it may be elevated under certain inflammatory conditions and give a false indication of storage iron. The higher recommended level for serum ferritin in hemodialysis patients is based on the information showing lower ESA doses and improved response to iron at this level of ferritin.[53] Previous versions of the K/DOQI anemia guidelines recommended an upper level for TSat of 50% (0.50) and serum ferritin of 800 ng/mL (800 µg/L) to reduce the risk of iron overload. No upper level for these iron indices has been established in the current recommendations; however, the guidelines state that there is insufficient evidence to recommend routine administration of IV iron if the patient's serum ferritin level is greater than 500 ng/mL (500 µg/L).[53] There is now evidence, however, to support administration of IV iron in anemic hemodialysis patients (Hb less than 11 g/dL [110 g/L; 6.83 mmol/L]) with a low TSat (less than 25% [0.25]) and elevated ferritin (500–1200 ng/mL[500–1200 µg/L]).[36] Since ferritin is an acute-phase reactant the decision of whether to give IV iron in conditions of elevated ferritin must be based on objective parameters such as TSat and Hb in addition to the clinical condition of the patient (e.g., infection, inflammation).

Nonpharmacologic Therapy

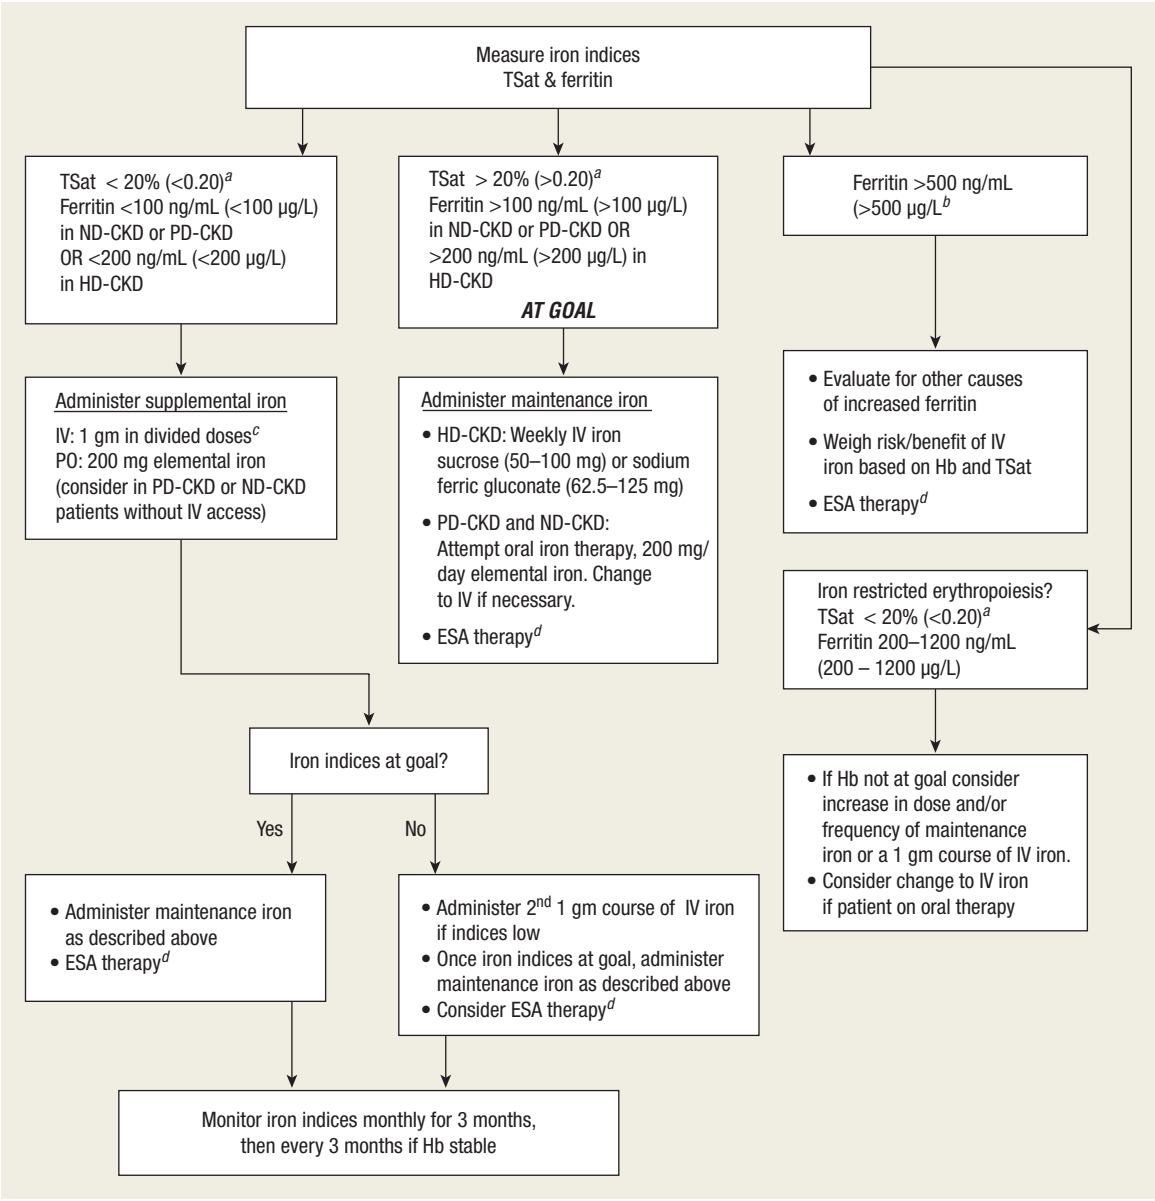
Nonpharmacologic therapy for anemia of CKD includes maintaining adequate dietary intake of iron as well folate and B_{12}. Patients on hemodialysis or peritoneal dialysis should be routinely supplemented with water-soluble vitamins (including B_{12} and folate) as these vitamins are often depleted with dialysis therapy. A relatively small amount of dietary iron, approximately 1 to 2 mg (or approximately 10%), is absorbed each day, primarily in the duodenum. Although there is some debate as to whether GI absorption of iron is significantly altered in patients with severe CKD, it is clear that oral intake from dietary sources alone is insufficient to meet the increased iron requirements from initiation of ESA therapy.[53]

Pharmacologic Therapy

9 Pharmacologic therapy for anemia of CKD is based upon a foundation of ESA therapy to correct erythropoietin deficiency and iron supplementation to correct and prevent iron deficiency caused by ongoing blood loss and increased iron demands associated with the initiation of erythropoietic therapy (Figs. 53–3 and 53–4). Iron therapy is first-line therapy for anemia of CKD if iron deficiency is diagnosed, and for some patients the target Hb may be achieved without concomitant ESA therapy. For most individuals with advanced CKD, however, combined therapy with iron and an ESA is often required to effectively stimulate erythropoiesis.

Iron Supplementation Options for iron supplementation include oral and IV therapy (Tables 53–6 and 53–7). Oral iron preparations differ in their content of elemental iron: ferrous salts (ferrous sulfate, ferrous fumarate, and ferrous gluconate), polysaccharide iron complex, and a heme iron polypeptide formulation. Five IV iron products are currently available in the United States (see Table 53–7): two composed of iron dextran (INFeD, molecular weight [MW] 96 kDa; and Dexferrum, MW 265 kDa), sodium ferric gluconate (Ferrlecit, MW 350 kDa), iron sucrose (Venofer, MW 43 kDa), and ferumoxytol (Feraheme, MW 750 kDa).[54–56]

Pharmacology and Mechanism of Action. Iron supplements provide the elemental iron required for production of hemoglobin and its subsequent incorporation in red blood cells,



ND-CKD = nondialysis CKD patients; PD-CKD = peritoneal dialysis patients; HD-CKD = hemodialysis patients

[a] Or CHr < 29 pg/cell in hemodialysis patients

[b] Clinical judgement should be used to determine if iron supplementation should be continued when ferritin > 500 ng/mL (>500 µg/L)

[c] Sodium ferric gluconate, iron sucrose, and iron dextran may be administered in divided doses over 8–10 HD sessions for HD-CKD patients. Administer in divided doses over a prolonged administration time (e.g. up to 400 mg iron sucrose over 2.5 hrs) for PD-CKD and ND-CKD patients. Ferumoxytol may be administered as two 510-mg doses. Test dose required for iron dextran.

[d] See Figure 53-4.

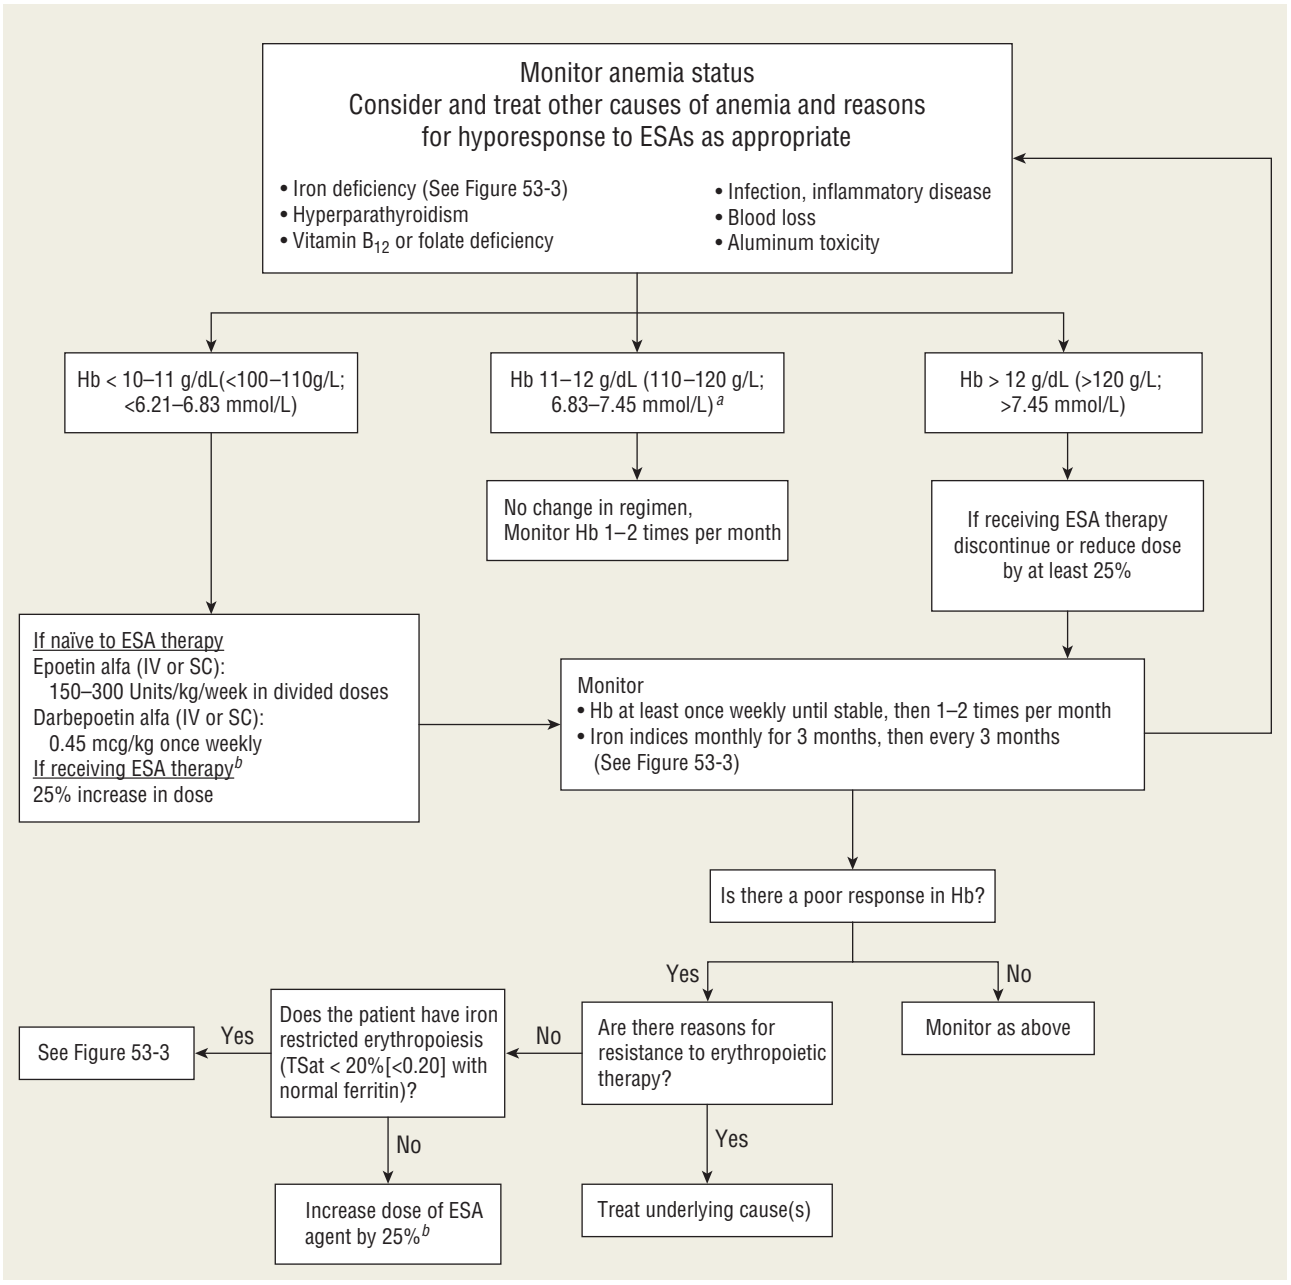
FIGURE 53-3. Algorithm for iron therapy in the management of the anemia of CKD. (ESA, erythropoietic-stimulating agent; Hb, hemoglobin; TSat, transferrin saturation; ND-CKD, nondialysis CKD patients; PD-CKD, peritoneal dialysis patients; HD-CKD, hemodialysis patients.)

the net result of which is an increase in the transportation of oxygen to tissues.

Bioavailability. Approximately 10% of orally administered iron is absorbed in the duodenum and upper jejunum. Absorption of iron is decreased by food and achlorhydria. The heme form of oral iron binds to a different receptor in the GI tract than nonheme iron, is absorbed to a greater extent, and may be better tolerated.[57] Some oral iron formulations also include ascorbic acid to enhance iron absorption.

Intravenous iron preparations are colloids that consist of an iron-containing core that is surrounded by a carbohydrate shell to stabilize the iron complex. Available agents differ in the size of the core and the composition of the surrounding carbohydrate. These differences affect the rate of dissociation of iron from the complex to phagocytes within the reticuloendothelial system where iron is either stored or released to the extracellular carrier protein transferrin, which transports iron to the bone marrow for red blood cell production. The half-lives of the available IV iron formulations differ: ferric gluconate (1 hour), iron sucrose (6 hours), ferumoxytol (15 hours), and iron dextran (40 to 60 hours).[54,56,58]

Efficacy, Dosage, and Administration. Although supplementation using oral preparations may seem more practical than IV administration, oral iron therapy is limited by poor absorption and nonadherence with therapy primarily due to adverse effects and,



[a]Note that the goal Hb is 10–12 g/dL (100–120 g/L; 6.21–7.45 mmol/L) based on FDA labeling for ESAs

[b]Do not adjust ESA dose more frequently than every 4 weeks as a general rule

FIGURE 53-4. Algorithm for erythropoietic stimulating agent therapy in the management of the anemia of CKD. (ESA, erythropoietic-stimulating agent; Hb, hemoglobin; SC, subcutaneous; TSat, transferrin saturation.)

thus, it is a challenge to achieve goal iron indices. If oral therapy is initiated, the recommended dose is 200 mg of elemental iron per day (see Table 53–6). Either oral or IV administration of iron is recommended in early-stage CKD and the peritoneal dialysis population. Oral iron supplementation is more convenient for these patients, who do not have regular IV access; however, at some point they are likely to require IV iron supplementation to meet iron needs and correct absolute iron deficiency, especially if receiving an ESA.

In patients with ESRD, GI absorption of iron is often inadequate to meet the increase in iron demand from ESA therapy and chronic blood loss in the hemodialysis population. K/DOQI guidelines recommend IV iron as the preferred route of administration in the hemodialysis population.[53] Parenteral iron improves the responsiveness to ESA therapy and reduces the dose required to achieve and maintain the target Hb in hemodialysis patients. For the hemodialysis population typical repletion dosing regimens are 100 mg as iron sucrose or iron dextran over 10 dialysis sessions, or 125 mg of sodium ferric gluconate over 8 dialysis sessions (see Table 53–7). Ferumoxytol is administered as 510 mg at a rate not to exceed 30 mg per second (1 mL per second) with a second dose given within 3 to 8 days.[56] Administration of 1 g of IV iron is recommended to initially replete hemodialysis patients with an absolute iron deficiency; however, without ongoing iron supplementation, many patients quickly become iron deficient. To prevent iron deficiency maintenance doses of IV iron are administered in hemodialysis patients (e.g., iron sucrose or iron dextran 25 to 100 mg/wk; sodium ferric gluconate 62.5 to 125 mg/wk) based on evidence of improved Hb and lower ESA doses with these regimens.[53,59]

TABLE 53-6 Oral Iron Preparations

Iron Product	Common Agents and Available Units	Amount of Elemental Iron Per Unit	Number of Units Per Day[a]
Ferrous sulfate	Fer-In-Sol (75 mg/0.6 mL)	75 mg	2–3
	Feosol (200 mg)	65 mg	3–4
	Ferrous sulfate, various preparations (325 mg)	65 mg	3–4
	Slow FE (160 mg)	50 mg	4
Ferrous fumarate	Ferrous fumarate, various preparations (300 mg)	99 mg	2
	Femiron (63 mg)	20 mg	10
	Nephro-Fer (350 mg)	115 mg	2
	Vitron-C (65–125 mg)	65 mg	3
Ferrous gluconate	Ferrous gluconate, various (325 mg)	36 mg	5
	Fergon (240 mg)	27 mg	6
Polysaccharide iron	Niferex (50 mg)	50 mg	4
	Hytinic (150 mg)	150 mg	1–2
Heme iron polypeptide	Proferrin-ES (12 mg)	12 mg	17

[a]Number of units per day depends on the amount of elemental iron per unit; 200 mg elemental iron per day is recommended.

Iron administration in patients with what is known as *iron restricted erythropoiesis* (also referred to as *functional iron deficiency*) is more questionable. Under these conditions a trial of IV iron therapy may be warranted if the Hb is less than the target of 11 g/dL (110 g/L; 6.83 mmol/L). A recent study conducted in ESA-treated anemic hemodialysis patients with a low TSat (<25% [<0.25]) and an elevated serum ferritin (>500 ng/mL [>500 µg/L]) showed a significantly greater Hb response rate in patients who received a 1 g course of IV iron as sodium ferric gluconate in conjunction with a 25% increase in ESA dose than in those who only received an increase in the ESA dose.[36]

Adverse Effects. Adverse effects of oral iron are primarily GI in nature and include constipation, nausea, and abdominal cramping. These adverse effects are more likely as the dose is escalated and may be present in more than 50% of patients receiving 200 mg of elemental iron per day. These unfavorable effects often discourage patients from taking these medications on a chronic basis. Some of these GI side effects can be minimized if oral iron products are taken with food; however, food decreases absorption of oral iron. Patients should initially be instructed to take oral iron on an empty stomach; however, if side effects lead to intolerance and nonadherence these agents can be administered with food, or an alternative agent may be prescribed.

Adverse effects of IV iron include allergic reactions, hypotension, dizziness, dyspnea, headaches, lower back pain, arthralgia, syncope, and arthritis. Some of these reactions, in particular hypotension, can be minimized by decreasing the dose or rate of infusion of iron. The most concerning potential consequence of IV iron administration is anaphylaxis. Anaphylactoid reactions to iron dextran have been reported in up to 1.8% of patients, with serious reactions including respiratory complications and cardiovascular collapse occurring in approximately 0.6%.[60] Such reactions are believed to be partly a response to antibody formation to the dextran component. Adverse reactions have been reported two to eight times more frequently in those receiving Dexferrum compared with INFeD.[61] Based on the labeling for all iron dextran products clinicians should (a) administer a test dose of 25 mg prior to the first therapeutic dose; if there are no signs or symptoms of an anaphylactic-type reaction then administer the full therapeutic dose; (b) observe for signs or symptoms of anaphylactic-type reactions during and after every administration; and (c) note that patients with a history of drug

TABLE 53-7 Intravenous Iron Preparations

Iron Compounds	FDA-Approved Indications	FDA-Approved Dosing	Warnings	Dose Ranges[a]
Iron Dextran (INFeD, Watson Pharma Inc., Morrisontown, NJ, and DexFerrum, American Regent, Inc.. Shirley, NY)[b]	Patients with iron deficiency in whom oral iron is unsatisfactory	IV push: 100 mg over 2 min (25-mg test dose required)	Black box (risk of anaphylactic reactions)	25–1,000 mg
Sodium ferric gluconate (Ferrlecit, Sanofi-Aventis, Dagenham, Essex, England)[c]	Adult and pediatric HD patients age 6 years and older receiving ESA therapy	IV push (adult): 125 mg over 10 min IV infusion (adult): 125 mg in 100 mL of 0.9% NaCl over 60 min IV infusion (pediatric): 1.5 mg/kg in 25 mL of 0.9% NaCl over 60 min; maximum dose 125 mg	General	62.5–1,000 mg
Iron sucrose (Venofer, American Regent, Inc., Shirley, NY)[d]	HD patients with CKD receiving ESA therapy	IV push: 100 mg over 2–5 min IV infusion: 100 mg in maximum of 100 mL of 0.9% NaCl over 15 min	General	25–1,000 mg
	Nondialysis-CKD patients receiving or not receiving ESA therapy	IV push: 200 mg over 2–5 min on 5 different occasions within 14-day period		
	PD patients receiving ESA therapy	IV infusion: 2 infusions, 14 days apart, of 300 mg in a maximum of 250 mL of 0.9% NaCl over 1.5 h, followed by 1 infusion, 14 days later, of 400 mg in a maximum of 250 mL of 0.9% NaCl over 2.5 h		
Ferumoxytol (Feraheme, AMAG Pharmaceuticals, Lexington, MA)[e]	Adult patients with iron-deficiency anemia associated with chronic kidney disease	IV: 510 mg (17 mL) as a single dose, followed by a second 510 mg dose 3–8 days after the initial dose (rate of 1 mL or 30 mg/second)	General	510 mg

CKD, chronic kidney disease; ESA, erythropoietin-stimulating agent; HD, hemodialysis; PD, peritoneal dialysis.
[a]Small dosing ranges (e.g., 25–150 mg per week) generally used for maintenance regimens. Larger doses (e.g., 1 g) should be administered in divided doses.
[b]Supplied in 2-mL single-dose vials containing 50 mg of elemental iron per mL.
[c]Available in colorless glass ampules containing 62.5 mg elemental iron (12.5 mg/mL).
[d]Supplied in 5-mL single-dose vials containing 100 mg elemental iron (20 mg/mL).
[e]Supplied as a 17-mL single-use vial containing 510 mg elemental iron (30 mg/mL).

allergies may be at increased risk of anaphylactic-type reactions.[62,63] The potential for increased risk of reactions with concomitant use of angiotensin-converting enzyme inhibitors and iron dextran is also highlighted in the labeling for iron dextran, and a statement is included to clarify that there are differences in the chemical characteristics and clinical effects of available iron dextran products (e.g., Dexferrum and INFeD) since these agents are often erroneously considered interchangeable.[63]

The risk of adverse events with iron dextrans was particularly influential in product selection prior to the availability of sodium ferric gluconate, iron sucrose, and ferumoxytol. These IV iron formulations have a better safety record than either of the iron dextran products, based on their history of use in Europe over the last 4 decades (sodium ferric gluconate and iron sucrose) and data in the United States since these products were approved.[61,64] These newer agents do not require administration of a test dose prior to administration of the full dose. As a precaution with all IV preparations, patients should be observed during and immediately following administration for any adverse reactions.

Administration of IV iron also introduces a risk of iron overload. Deposition of excess iron may affect several organ systems, leading to hepatic, pancreatic, and cardiac dysfunction. Bone marrow biopsy provides the most definitive diagnosis of iron overload, but because it is an extremely invasive procedure, it is not widely employed in most clinical settings. Maintaining serum ferritin and TSat values that demonstrate efficacy in preventing iron deficiency yet are safe is the most reasonable approach to minimize the risk of iron toxicity. The challenge is in defining these upper limits, particularly for serum ferritin, which may be elevated in inflammatory conditions and not reflective of true iron stores in such situations. If symptomatic overload does occur, deferoxamine (Desferal) or phlebotomy may be necessary.

Dosage Considerations. The safety and efficacy of high-dose IV iron regimens have been evaluated to determine the most cost-effective and efficacious dosing strategies. Iron dextran has been safely administered to dialysis patients in total-dose infusions ranging from 400 mg to 2 g.[65] Similar high-dose regimens of 500 mg have also been safely administered to patients with stage 3 or 4 CKD.[66] Sodium ferric gluconate has been safely administered at doses of 250 mg infused over 1 hour (4.2 mg/min).[67] In this same evaluation, 19 doses greater than 250 mg were administered; 1 dose of 312.5 mg, 14 doses of 375 mg, and 4 doses of 500 mg, with infusion rates varying from 1.22 mg/min to 25 mg/min. No serious adverse events were reported, although nonserious events, such as pruritus, did occur in 4 of the 144 patients who received the 250 mg dose. If doses higher than those currently approved are used in practice, they should be administered over a prolonged time period (e.g., at least 2–3 hours). Iron sucrose at doses of up to 500 mg administered over 3 hours on consecutive days has been successful in maintaining iron stores without causing serious adverse events.[68] When administered over a shorter time period this same dose was associated with dizziness, hypotension, and nausea.[69] In this same evaluation the administration of lower doses of 200 to 300 mg given over 2 hours resulted in fewer adverse events. Higher-dose regimens for iron sucrose have been approved in patients with early-stage CKD and peritoneal dialysis patients (see Table 53–7), populations in whom administration of higher doses are more convenient as these patients are seen less frequently by healthcare providers than the hemodialysis population.[58] Ferumoxytol was approved in 2009 for use in the adult CKD population, including dialysis and nondialysis patients. The approved dose is 510 mg administered at a rate of up to 30 mg per second, a higher dose and administration rate compared with other available IV iron formulations.[70,71]

Although there are conflicting reports, most clinicians believe that exposure to iron may contribute to the risk of bacterial infection because iron is used by microorganisms for metabolic functions. The association of IV iron with oxidative stress, acceleration of atherosclerosis, and other cardiovascular conditions has also been suggested.[72,73] These potential long-term risks of IV iron therapy are not clearly defined, and there are no data confirming unequivocally that aggressive use of IV iron in CKD patients treated with ESA therapy increases patient morbidity or mortality.

As a superparamagnetic oxide, ferumoxytol may affect the diagnostic ability of magnetic resonance imaging studies; therefore, these imaging studies should be done prior to administration of ferumoxytol when possible. These effects may persist for up to 3 months following administration of ferumoxytol. Ferumoxytol will not interfere with x-ray, computed tomography, positron emission tomography, single photon emission computed tomography, ultrasonography, or nuclear medicine imaging.[56]

Erythropoietic-Stimulating Agent Therapy

Pharmacology and Mechanism of Action. Erythropoietic-stimulating agents (ESAs) are glycoproteins manufactured by recombinant DNA technology that have the same biologic activity as endogenous erythropoietin. Available ESAs in the United States include epoetin alfa (distributed as Epogen by Amgen, Inc., Thousand Oaks, CA; and Procrit by Ortho Biotech, Johnson & Johnson, Raritan, NJ) and darbepoetin alfa (Aranesp by Amgen, Inc., Thousand Oaks, CA). Epoetin beta is available from several sources outside the United States (e.g., NeoRecormon, F. Hoffmann–La Roche).

Since 1989, epoetin alfa has been the mainstay of therapy for anemia of CKD. Darbepoetin alfa was approved for treatment of anemia of CKD in September 2001. Darbepoetin alfa differs from epoetin alfa by the addition of two N-linked carbohydrate side chains, which increases the molecular weight (~37 kDa for darbepoetin compared with 30.4 kDa for epoetin alfa). The increase in sialic acid content decreases the affinity of darbepoetin for the erythropoietin receptor, but extends the half-life compared with epoetin alfa.[74]

Pharmacokinetics and Pharmacodynamics. Epoetin alfa may be administered by either the IV or the subcutaneous (SC) route. Although bioavailability with SC administration is approximately 30% to 36% that of IV, the prolonged absorption phase leads to an extended half-life of 24 hours with SC administration compared to 8.5 hours with IV administration.[75,76] The prolonged half-life with SC administration leads to a more sustained physiologic stimulation of erythroid precursors. Trials have shown that the same target Hb can be achieved and maintained at SC epoetin doses 15 to 30% lower than IV doses.[53,77] Darbepoetin alfa has a longer half-life than does epoetin alfa (25.3 hours and 48.8 hours after IV and SC administration, respectively).[78] More recent information based on studies with prolonged sampling times compared with the original pharmacokinetic studies have reported an even longer half-life of darbepoetin of 70 to 105 hours with SC administration.[75] The prolonged half-life of darbepoetin offers the advantage of less-frequent dosing, starting at once a week or once every other week when given IV or SC. This is of particular benefit in stage 4 and 5 CKD patients who are not yet receiving dialysis and those receiving peritoneal dialysis. Prolonged dosing intervals, as infrequent as once every 4 weeks, have also been effective in maintaining target Hb in many CKD patients, including nondialysis CKD and ESRD patients.[79,80]

The pharmacodynamics of epoetin and darbepoetin are important to consider when evaluating response to therapy. With initiation of ESA therapy or a change in dose, the Hb may begin to rise as the result of demargination of reticulocytes; however, it takes approximately 10 days before erythrocyte progenitor cells mature

and are released into the circulation. The Hb continues to increase until the life span of the cells stimulated by epoetin or darbepoetin is reached (mean 2 months; range 1 to 4 months in patients with ESRD). At this point a new steady state is achieved (i.e., the rate at which red blood cells are being produced equals the rate at which they are leaving the circulation). For this reason it is important to evaluate the Hb response over several weeks as opposed to making changes in the dosing regimen prematurely.

Efficacy. Patients will generally respond to ESA therapy in a dose-related fashion unless there are confounding factors present that may cause resistance to therapy or failure to respond as defined by the K/DOQI guidelines.[53] The most common causes of resistance are iron deficiency, acute illness, catheter insertion, hypoalbuminemia, elevated C-reactive protein, chronic bleeding, aluminum toxicity, malnutrition, hyperparathyroidism, cancer and chemotherapy, AIDS, inflammation, and infection. Erythropoietic therapy may be continued in the infected or postoperative patient, even though increased doses are often required to maintain or slow the rate of decline in Hb. Deficiencies in folate and vitamin B_{12} should also be considered as potential causes of resistance to ESA therapy, as both are essential for optimal erythropoiesis.

Medicare has developed new clinical performance measures (CPMs) for ESRD providers that emphasize both an upper and a lower limit of Hb. Of note the limits advocated in the new CPMs are based on FDA labeling (Hb 10–12 g/dL[100–120 g/L; 6.21–7.45 mmol/L]) as opposed to the K/DOQI guidelines (Hb 11–12 g/dL [110–120 g/L; 6.83–7.45 mmol/L]).[81]

Adverse Effects. Hypertension is the most common adverse event reported with epoetin alfa and darbepoetin alfa and may be associated with the rate of rise in Hb.[53] Protocols established in some clinical settings, primarily in outpatient dialysis clinics, sometimes recommend withholding ESA therapy if blood pressure is above a defined threshold. K/DOQI guidelines for anemia do not recommend withholding ESA therapy for elevated blood pressure, but instead advocate more judicious use of antihypertensive agents and dialysis to control blood pressure; however, according to FDA-approved product labeling ESAs should not be used in those with uncontrolled blood pressure.[74,76,82] Seizures have occurred in patients treated with epoetin, particularly within the first 90 days of starting therapy. Vascular access thrombosis may also be more frequent during ESA therapy.[76,83] The potential for these adverse effects calls for close monitoring of the rate of rise in Hb, changes in blood pressure, and monitoring neurologic symptoms following initiation of therapy or a change in ESA dose.

Data demonstrating a higher risk of adverse outcomes in CKD patients treated more aggressively to Hb targets above 12 g/dL (120 g/L; 7.45 mmol/L) with ESAs prompted the FDA to issue a warning in March 2007 about safety concerns of higher Hb targets. Manufacturers revised the ESA product labeling to include updated warnings, a new boxed warning, and modifications to the dosing instructions. The new boxed warning advises healthcare providers to monitor Hb and to adjust the ESA dose to maintain the lowest hemoglobin level needed to avoid blood transfusions. Of note the Hb target in the product labeling for ESAs is 10 to 12 g/dL (100–120 g/L; 6.21–7.45 mmol/L),[74,76,82] An FDA-approved medication guide describing the risks of ESA use must also be given to patients receiving ESA therapy.

Neutralizing antibodies to ESAs have been identified in a relatively small number of patients treated with ESAs; approximately 200 cases were reported between 1998 and 2004.[84] These patients develop antibody-mediated pure red cell aplasia (PRCA), which results in an absolute resistance to ESA therapy and reliance on blood transfusions as the primary therapeutic option. Cases were mostly reported between 1998 and 2002 and occurred in parallel with the increase in SC administration, primarily with one epoetin alfa product manufactured outside the United States, Eprex (Johnson & Johnson, Manati, Puerto Rico). Differences in this formulation that were noted at the time of the increase in PRCA cases were the substitution of human albumin with polysorbate 80 and use of uncoated rubber stoppers in the single-dose syringes, factors that in combination may have increased the immunogenicity of SC-administered epoetin alfa. Changes in packaging of these syringes led to a decrease in PRCA case reports. Although the case reports of antibody-associated PRCA are relatively few in number, further evaluation for PRCA should be considered for patients receiving ESA therapy who develop a rapid decrease in Hb level (rate of 0.5–1.0 g/dL/wk [5–10 g/L/wk; 0.31–0.62 mmol/L/wk]), become transfusion dependent, and have an absolute reticulocyte count of less than 10,000/μL (10×10^9/L) with a normal platelet and white blood cell count. Discontinuation of ESA therapy is recommended in antibody-mediated PRCA because antibodies are cross-reactive and continued exposure may lead to anaphylactic reactions. Immunosuppressive therapy has been effective in up to 50% of patients with PRCA.[84] A peptide-based erythropoietin-receptor agonist, hematide, an investigational agent that has a different amino acid sequence than native or recombinant erythropoietin, has been shown to stimulate erythropoiesis in patients with PRCA or hyporesponsiveness due to antierythropoietin antibodies and may provide another option in the future for individuals with PRCA.[85]

Drug–Drug Interactions. No significant drug interactions have been reported with the available ESAs.

Dosing and Administration. Recommended starting doses of epoetin alfa are 50 to 100 Units/kg IV or SC three times per week for hemodialysis patients.[76] Less frequent dosing is preferred for stage 4 CKD patients and peritoneal dialysis patients since these patients are seen in the outpatient clinic setting on a relatively infrequent basis.[86,87] Improved erythropoiesis and reduced transfusion requirements were observed in patients with anemia (Hb <10 g/dL [<100 g/L; <6.21 mmol/L]) who received once-weekly SC doses of 10,000 Units of epoetin alfa.[86] Monthly dosing intervals for epoetin alfa SC have also been effective in maintaining target Hb values in this population.[87]

The starting dose of darbepoetin alfa in patients not previously receiving ESA therapy is 0.45 mcg/kg IV or SC administered once weekly. A conversion table for patients who are to be switched from epoetin alfa (Units per week) to darbepoetin alfa (micrograms per week) is available in the package insert for darbepoetin.[74] The usual dosing frequency of darbepoetin is weekly for patients previously receiving epoetin two to three times per week and every other week for patients receiving epoetin once weekly. Extended dosing intervals of darbepoetin as infrequent as every 4 weeks have been successful in maintaining Hb levels.[75]

The IV route of administration is preferred for most hemodialysis patients.[53] Subcutaneous administration of ESAs is preferable for peritoneal dialysis patients and the nondialysis CKD population because these patients do not usually have regular IV access. Dose adjustments should be made based on Hb response with consideration of the recent data on risks associated with higher Hb levels and rate of rise in Hb. A general recommendation is to reduce the ESA dose by 25% if the Hb is approaching 12 g/dL (120 g/L; 7.45 mmol/L) or if the Hb increases by more than 1 g/dL (10 g/L; 0.62 mmol/L) in any 2-week period. A 25% increase in dose may be considered if the Hb is below target range and has not increased by 1 g/dL (10 g/L; 0.62 mmol/L) after 4 weeks of ESA treatment and if no causes of resistance to the ESA have been identified.[74,82] Figures 53–3 and 53–4 provide an algorithmic approach to management of anemia using ESAs and iron therapy in patients with ESRD.

Transfusions and Adjunct Therapies Red blood cell transfusions are currently a third-line treatment option for anemia of

CKD. Red blood cell transfusions carry many risks and therefore should only be used in select situations, such as acute management of symptomatic anemia, following significant acute blood loss, and prior to surgical procedures that carry a high risk of blood loss, with the goal of preventing inadequate tissue oxygenation or cardiac failure. l-Carnitine supplementation and vitamin C were previously suggested as adjunctive treatments of anemia associated with kidney disease but are not recommended in the K/DOQI guidelines because of the lack of evidence supporting improved anemia management with these therapies.[88]

Pharmacoeconomic Considerations

Pharmacoeconomic considerations in the management of anemia of CKD relate primarily to the costs associated with ESAs and IV iron to sustain erythropoiesis. In the outpatient dialysis environment there is a fee-for-service reimbursement system that was implemented by the federal government through the Medicare system. As a general practice, dialysis facilities are reimbursed for ESAs and IV iron at a rate based on the success of maintaining Hb within specific targets, which have changed as guidelines and clinical performance measures for anemia management have been updated. This fee-for-service reimbursement system led to an increase in average ESA doses; the Medicare cost of ESAs was $1.8 billion in 2007.[2] USRDS data indicate that these costs have stabilized. This is due, in part, to changes in the composite rate administered to dialysis facilities, limits on reimbursement for ESAs if Hb levels exceed upper limits, and the recent warnings about ESA safety, which have led to a decrease in ESA use and target Hb levels.

The results of CHOIR, CREATE, and the NHCT prompted CMS to develop a plan for bundling ESAs along with other separately billable drugs into a single payment system to provide an incentive for dialysis facilities to use ESAs more sparingly and reduce costs. This "bundling" of payments for dialysis services is designed to reduce financial incentives for utilization of ESAs and other previously separately billable drugs. Included in the bundled payment are services provided for the dialysis procedure itself that were included in the previous composite rate, separately billable injectable drugs administered during the dialysis procedure (such as ESAs, vitamin D analogs, iron, antibiotics) and their oral equivalents, and separately billable laboratory tests related to the treatment of ESRD. The proposed payment plan for this bundling system was released in the fall of 2009 and is currently in draft form. Once finalized this bundling system is planned for implementation in January 2011.

Evaluation of Therapeutic Outcomes

Iron status should be assessed every month during initial ESA treatment, and every 3 months for those receiving a stable ESA regimen or for those hemodialysis patients not treated with an ESA.[53] For all ESAs, the initial dose and subsequent adjustments should be determined by the patient's Hb level relative to the target Hb level, and the most recent observed rate of increase in Hb. Hemoglobin should be monitored at least monthly in patients receiving ESA therapy, although more frequent monitoring (e.g., every 1–2 weeks) is warranted after initiation of an ESA or following a dose change until the Hb is stable. The response to ESA therapy should be evaluated at least over 2 to 4 weeks before a change in the dose of epoetin alfa or darbepoetin alfa is made. New FDA and CMS recommendations now advise healthcare providers to withhold ESA therapy if the Hb is >12 g/dL (>120 g/L; >7.45 mmol/L); some clinicians, however, may institute a dosage reduction of ≥25% to prevent drastic shifts in Hb levels. An algorithm for anemia management is depicted in Figures 53–3 and 53–4.

CKD-MINERAL AND BONE DISORDER (CKD-MBD) AND RENAL OSTEODYSTROPHY

Desired Outcome

The overall goal for management of CKD-MBD is to "normalize" the biochemical parameters and prevent the detrimental consequences, including renal osteodystrophy, cardiovascular and extravascular calcifications, and the associated morbidity and mortality. Unfortunately prospective trials to evaluate the effect of controlling CKD-MBD on these outcomes are limited. At present the K/DOQI (U.S. guidelines) and KDIGO (international guidelines) can be used to guide clinical decision making; however, there are notable differences in these guidelines.[18,22]

CLINICAL CONTROVERSY

K/DOQI clinical practice guidelines for bone metabolism and disease in CKD have been available in the United States since 2003. Targets for calcium, phosphorus, calcium-phosphorus product, and PTH are defined based on opinion and evidence, when available, and have led to development of standardized protocols. In 2009 KDIGO international guidelines for CKD-MBD were published. Given the lack of randomized, controlled trials to support specific target levels for calcium, phosphorus, and PTH the recommendations for target levels and treatment approaches are much more general. Healthcare providers are left to use clinical judgment and new information as it becomes available to sort out the discrepancies in these guidelines where they exist.

The K/DOQI recommended targets for calcium, phosphorus, Ca × P product, and PTH based on the stage of CKD are shown in Table 53–4.[22] The calcium should be corrected for albumin level. The recommended corrected serum calcium for patients with stage 3 or 4 CKD is within the normal range, whereas the proposed range for patients with stage 5 CKD is slightly lower than the normal range. This lower range for calcium in stage 5 CKD patients is based on observations of an increased risk of soft tissue and vascular calcifications in this population, particularly in those individuals with an elevated Ca × P product. Serum phosphorus concentrations should be within the normal range, with higher concentrations acceptable in stage 5 CKD, in part, because of the challenges of lowering phosphorus. The proposed Ca × P product of 55 mg^2/dL^2 (4.4 $mmoL^2/L^2$) is much lower than the previous recommendation of 65 to 70 mg^2/dL^2 (5.2 to 5.7 $mmoL^2/L^2$). The PTH values recommended for patients with stage 4 or 5 CKD are above the normal range to prevent oversuppression of PTH and reduce the risk of adynamic bone disease. Serum aluminum levels should also be maintained below 20 μg/L (0.74 μmol/L) to minimize the risk of developing aluminum toxicity, a contributing factor to bone disease.[22]

Based on a lack of randomized, controlled trials showing improved outcomes with control of calcium, phosphorus, and PTH within narrowly defined ranges, KDIGO does not define specific targets for these parameters. KDIGO recommends maintaining serum phosphorus within the normal range for stage 3 to 5 CKD patients and lowering phosphorus toward the normal range for dialysis patients. They propose that calcium should be maintained within the normal range for all CKD patients. KDIGO also supports evaluation of trends in calcium and phosphorus values individually as opposed to attempting to achieve a target Ca × P product.[18] Overall,

these recommendations for calcium and phosphorus do not differ drastically from K/DOQI. Clinicians do need to consider risk of calcifications in the stage 5 CKD population and whether a lower target calcium is warranted in individual patients. No specific PTH target range is advocated by KDIGO, but rather the recommendation is to evaluate trends and consider intervention in individuals with values above the upper range for the assay method used. In the dialysis population a broad range for PTH of two to nine times the upper normal limit of the assay is suggested.

⑩ Management of PTH, phosphorus, and calcium balance is important in preventing CKD-MBD, ROD, and cardiovascular and extravascular calcifications. Patients with ESRD usually require a combination of dietary intervention, phosphate-binding medications, vitamin D, and calcimimetic therapy to achieve these goals.

Nonpharmacologic Therapy

Dietary Phosphorus Restriction Dietary phosphorus restriction should be a first-line intervention for management of hyperphosphatemia in patients with CKD and should be initiated for most patients with stage 3, 4, or 5 CKD. The K/DOQI guidelines recommend phosphorus restriction to 800 to 1,000 mg/day when the upper levels of serum phosphorus are reached (see Table 53–4).[22] This recommendation also applies to patients with PTH levels above the recommended range given the evidence that lowering phosphorus ingestion directly decreases PTH synthesis and secretion.[89] The challenge with dietary restriction of phosphorus is providing enough protein to prevent malnutrition, a common problem in the ESRD population because foods high in phosphorus are generally high in protein. Examples of foods or beverages that contain high amounts of phosphorus include meats, dairy products, dried beans, nuts, colas, peanut butter, and beer. Nutritional goals must be evaluated on an individual basis, preferably by a dietitian specializing in the care of CKD patients. Dialysis patients require a higher protein intake (1.2–1.3 g/kg per day), making restriction of phosphorus even more challenging. Removal of phosphorus does occur with peritoneal dialysis and hemodialysis (approximately 2–3 g/wk, dependent on the dialysis prescription); however, intermittent dialysis alone does not usually control hyperphosphatemia.

One of the most common obstacles to the success of dietary phosphorus restriction is patient noncompliance because of the poor palatability and inconvenience. Regular counseling by a dietitian is necessary to design a realistic diet that works with the patient's lifestyle.

Dialysis Hemodialysis and peritoneal dialysis lower serum phosphorus and calcium, the extent to which is dependent on the concentration of both entities in the dialysate and the duration of dialysis. K/DOQI recommends the dialysate calcium concentration in hemodialysis or peritoneal dialysis should be 2.5 mEq/L (1.25 mmol/L).[22] KDIGO suggests a dialysate calcium concentration of 2.5 to 3.0 mEq/L (1.25–1.50 mmol/L).[18] Dialysis alone cannot control these parameters, and dietary and pharmacologic interventions are also required in the majority of dialysis-dependent ESRD patients.

Parathyroidectomy Parathyroidectomy is a therapeutic option for patients with severe CKD-MBD who do not respond to pharmacologic therapy. The K/DOQI guidelines recommend surgery for those patients with persistently elevated PTH (PTH >800 pg/mL [>800 ng/L]) associated with hypercalcemia and/or hyperphosphatemia that are refractory to medical therapy.[22] Surgical approaches include either subtotal parathyroidectomy or total parathyroidectomy with autotransplantation of parathyroid tissue to an accessible site, such as the forearm. Postoperative hypocalcemia, hypophosphatemia, and hypomagnesemia may occur because of a marked increase in bone production in relation to bone absorption ("hungry bone syndrome"). Following surgery frequent monitoring of calcium and phosphorus is necessary as described in Chapter 59. Treatment with supplemental calcium and vitamin D may be required for weeks or months.

Pharmacologic Therapy

Phosphate-Binding Agents

Pharmacology and Mechanism of Action. Drugs that bind dietary phosphorous in the GI tract form insoluble phosphate compounds that are excreted in feces, thus reducing phosphorus absorption and serum phosphorus concentrations. A variety of phosphate-binding agents are available, including elemental calcium-, lanthanum-, aluminum-, and magnesium-containing compounds, and the nonelemental agent sevelamer carbonate (Table 53–8). Patients must be instructed to take these agents with meals to maximize the binding of phosphorus in the GI tract.

Efficacy. Oral calcium compounds are well established as first-line agents for control of both serum phosphorus and calcium concentrations, at least in the early stages of CKD when hypocalcemia is more common. Calcium carbonate and calcium acetate are the primary preparations used; calcium citrate is also available but is not recommended since the citrate component increases aluminum absorption. The chloride salt is also not recommended because it is very astringent and unpalatable, and absorbed chloride may contribute to systemic acidosis. Calcium carbonate is marketed in a variety of dosage forms (see Table 53–8) and is relatively inexpensive. Unfortunately, many calcium carbonate products are considered food supplements and thus are not required by law to meet United States Pharmacopeia (USP) disintegration and dissolution requirements. In general, nationally advertised brands meet USP quality standards for disintegration and dissolution, but it is difficult to determine whether private label or house brands conform to these standards. Variability in gastric pH may also affect disintegration or dissolution, and thus phosphate-binding efficacy. Calcium carbonate is more soluble in an acidic medium and therefore should be administered prior to meals when stomach acidity is highest. In addition, acid-suppressing agents such as ranitidine and proton pump inhibitors may reduce the phosphate-binding activity of calcium carbonate by increasing gastric pH. Calcium acetate binds approximately twice as much phosphorus as calcium carbonate at comparable doses of elemental calcium.[22] Increased binding potency limits GI calcium absorption; however, calcium acetate is more soluble, and therefore better absorbed than calcium carbonate in an alkaline pH, which may explain the similar incidence of hypercalcemia with these agents. For patients with hypocalcemia, calcium carbonate or calcium acetate may also be given as a calcium supplement taken between meals to promote calcium absorption.

Although calcium-containing phosphate-binding agents continue to be used as first-line therapy, their chronic use may increase the risk for vascular and tissue calcification.[28] The K/DOQI guidelines recommend that the total dose of elemental calcium provided by calcium-containing binders not exceed 1,500 mg per day and the total daily intake of elemental calcium from all sources not exceed 2,000 mg.[22] Calcium-containing binders are not recommended for dialysis patients who have persistent elevations in serum calcium >10.2 mg/dL (>2.55 mmol/L) or PTH values <150 pg/mL (150 ng/L).[22] KDIGO guidelines suggest restricting the dose of calcium-containing binders in stage 3 to 5 CKD patients if hypercalcemia is present or if arterial calcification or adynamic bone disease (low bone turnover disease) is evident.[18] Since both of these recommendations regarding calcium intake are based primarily on opinion, clinicians in essence have to rely on their past experiences and clinical judgment as they individualize therapy for their patients.

TABLE 53-8 Phosphate-Binding Agents Used for the Treatment of Hyperphosphatemia in CKD Patients

Compound	Trade Name	Compound Content (mg)	Dose Titration[a]	Starting Doses	Comments
Calcium carbonate[b] (40% elemental calcium)	Tums Oscal-500 Caltrate 600	500, 750, 1,000, 1,250 1,250 1,500	Increase or decrease by 500 mg per meal (200 mg elemental calcium)	0.5–1 g (elemental calcium) three times a day with meals	First-line agent; dissolution characteristics and phosphate binding may vary from product to product Approximately 39 mg phosphorus bound per 1 g calcium carbonate
Calcium acetate (25% elemental calcium)	PhosLo	667	Increase or decrease by 667 mg per meal (168 mg elemental calcium)	0.5–1 g (elemental calcium) three times a day with meals	First-line agent; comparable efficacy to calcium carbonate with half the dose of elemental calcium Approximately 45 mg phosphorus bound per 1 g calcium acetate By prescription only
Sevelamer carbonate *Available as tablet and powder for oral suspension	Renvela	800	Increase or decrease by 800 mg per meal	800–1,600 mg three times a day with meals	First-line agent; lowers low-density lipoprotein cholesterol More expensive than calcium products; consider in patients at risk for extraskeletal calcification Associated with a lower risk of acidosis and GI adverse events than Renagel.
Sevelamer Hydrochloride	Renagel	400, 800	Increase or decrease by 1 tablet per meal	Same as Renvela	Same as Renvela, plus acidosis
Lanthanum carbonate	Fosrenol	500, 750, 1,000	Increase or decrease by 750 mg per day	750–1,500 mg daily in divided doses with meals	First-line agent; Available as chewable tablets
Aluminum hydroxide[b]	Alterna GEL	600 mg/5 mL	–	300–600 mg three times a day with meals	Not a first line agent; do not use concurrently with citrate-containing products Reserve for short-term use (4 weeks) in patients with hyperphosphatemia not responding to other binders

[a]Based on phosphorus levels, titrate every 2 to 3 weeks until phosphorus goal reached.
[b]Multiple preparations available that are not listed.

Sevelamer is a nonabsorbable, nonelemental hydrogel phosphate-binding agent. The hydrochloride salt of sevelamer was approved by the FDA in 2000; however, its use was associated with the development of acidosis in some CKD patients. The manufacturer therefore developed the carbonate formulation that provides an added buffering capacity and does not contribute to acidosis.[90] This formulation is available as a tablet and powder for oral suspension and will eventually replace sevelamer hydrochloride. Sevelamer effectively lowers phosphorus and has also been shown to significantly lower LDL and increase HDL cholesterol.[90,91] Whether sevelamer lowers the risk of calcification compared with calcium-containing binders is an issue of some debate. There are studies to support use of sevelamer over calcium-containing binders to decrease progression of arterial calcification in both dialysis and nondialysis CKD patients.[92] These findings have been refuted by other studies showing that sevelamer is associated with similar rates of vascular calcification compared with calcium acetate.[93] K/DOQI guidelines suggest using a noncalcium-containing binder in dialysis patients with severe vascular or soft tissue calcifications, although these are opinion-based recommendations.[22] KDIGO states that binder choice be made considering the stage of CKD, other factors of CKD-MBD such as risk of calcifications, and other therapies.[18]

Lanthanum carbonate is a phosphate binder approved for patients with ESRD. Short-term (6–28 weeks) and long-term (2–3 years) therapy with lanthanum has demonstrated efficacy in controlling phosphorus and maintaining PTH in the target range with less risk of hypercalcemia than calcium-containing binders.[94,95] Initial daily doses are in the range of 750 to 1,500 mg (administered in divided doses with meals) with doses of 1,500 to 3,000 mg often being required to maintain target phosphorus in ESRD patients. The poor GI absorption, which limits systemic effects, and high binding capacity with phosphorus makes this an attractive phosphate-binding agent, particularly when options other than calcium-containing binders are needed. Lanthanum is available as a chewable tablet, which may be appealing for some patients. Lanthanum carbonate (2,250 to 3,000 mg/day) was as effective in lowering serum phosphorus as sevelamer hydrochloride (4,800 to 6,400 mg/day) in hemodialysis patients.[96] The effect of lanthanum on progression of calcification has not been evaluated in clinical trials.

Aluminum salts were widely used in the 1980s as phosphate-binding agents because of their high binding potency. They should no longer be used as first line agents but rather reserved for acute treatment of severe hyperphosphatemia or used at low doses in combination with either calcium-containing binding agents or sevelamer in cases of hyperphosphatemia that is not responding to therapy with a single agent. According to K/DOQI guidelines, the duration of aluminum therapy should be limited to four weeks if these agents are used at all.[22]

Magnesium-containing antacids are also effective phosphate binders and may decrease the amount of calcium-containing binders necessary for control of phosphorus; however, their use is limited by the frequent occurrence of GI side effects (i.e., diarrhea) and the potential for magnesium accumulation.

Adverse Effects. Adverse effects of all phosphate binders are generally limited to GI side effects, including constipation, diarrhea, nausea, vomiting, and abdominal pain. The risk of hypercalcemia may necessitate restriction of calcium-containing binders use and/or a reduction in dietary intake. Aluminum binders have been associated with CNS toxicity and the worsening of anemia, whereas magnesium binder use may lead to hypermagnesemia and hyperkalemia.

Drug–Drug and Drug–Food Interactions. Calcium-containing phosphate-binding agents interfere with the absorption of several

oral medications that are commonly prescribed for CKD patients, including iron, zinc, and quinolone antibiotics. No drug interaction studies have been performed with sevelamer carbonate; however, studies with sevelamer hydrochloride have shown no drug interactions with digoxin, warfarin, metoprolol, enalapril, or iron. Coadministration with ciprofloxacin did, however, result in a 50% decrease in bioavailability of the antibiotic. This information is reported in the labeling for the newer formulation sevelamer carbonate.[97] Potential interactions between sevelamer and cyclosporine (decreased bioavailability of cyclosporine) and altered phosphorus binding in the presence of agents that increase gastric pH (e.g., omeprazole) have been reported.[98,99] Drug interaction studies with lanthanum, although limited, have shown that coadministration with warfarin, digoxin, and metoprolol did not affect the bioavailability of those agents.[100] In general, it is rational to separate the administration time of oral medications for which a reduction in bioavailability has a clinically significant effect (e.g., quinolones) from phosphate binders by at least 1 hour before or 3 hours after administration of the phosphate binder. This is a key patient-counseling recommendation as patients are often switched from one phosphate binder to another, and it is easier for them to remember this general concept regarding phosphate binders and other medications. Many phosphate binders are marketed as antacids or calcium supplements, and often CKD patients do not know why they have been prescribed these agents. Regular patient counseling is essential to improve adherence and minimize the potential for drug interactions.

Dosing and Administration. Initial dosing regimens for phosphate-binding agents and suggested dose titration schemes are shown in Table 53–8. Doses should be titrated to achieve the recommended serum phosphorus concentrations based on the patient's stage of CKD. The daily dose of elemental calcium should be limited in individuals with elevated calcium levels.

Vitamin D Therapy Vitamin D compounds include ergocalciferol (vitamin D_2) and cholecalciferol (vitamin D_3) that must be converted to the active form in the kidney. Calcitriol (1,25-dihydroxyvitamin D_3) is the most active form of vitamin D and is available as an oral formulation (Rocaltrol) as well as an IV formulation (Calcijex). The currently available vitamin D analogs include paricalcitol (19-nor-1,25-dihydroxyvitamin D_2; Zemplar) and doxercalciferol (1α-hydroxyvitamin D_2; Hectorol). Calcitriol or one of the vitamin D analogs is required for patients with severe kidney disease because these agents do not require conversion by the kidney to the biologically active form.

Pharmacology and Mechanism of Action. Active vitamin D suppresses PTH secretion by stimulating absorption of serum calcium by intestinal cells and through direct activity on the parathyroid gland to decrease PTH synthesis. As a result, the serum calcium concentration is raised and the parathyroid glands decrease the rate of secretion and formation of PTH. The set point for calcium (i.e., the calcium concentration at which PTH secretion is decreased by 50%), which is generally raised in CKD-MBD, is lowered when active vitamin D therapy is initiated. This indicates that a lower ionized calcium concentration is effective at suppressing secretion of PTH. All of these actions are mediated by the interaction of vitamin D with vitamin D receptors, which are located in many organs, including the parathyroid gland, GI tract, and kidney. Calcitriol also upregulates vitamin D receptors, which ultimately may reduce parathyroid hyperplasia. Unfortunately, the enhanced GI absorption of calcium and phosphorus with calcitriol therapy frequently leads to hypercalcemia and hyperphosphatemia. There is also evidence that hyperphosphatemia results in resistance to the PTH-suppressing effects of vitamin D and directly stimulates PTH release. These actions contribute to the increase in the Ca × P product, which is associated with soft-tissue and vascular calcifications.[22,25] Consequently, reasonable control of calcium and phosphorus must be achieved before initiation and during continued vitamin D therapy. This does not mean that vitamin D therapy should be withheld or discontinued in patients with a Ca × P product greater than 55 mg^2/dL^2 (4.4 $mmoL^2/L^2$). Rather interventions with agents with a lower risk of hypercalcemia and hyperphosphatemia, and more prudent use of phosphate binders to lower calcium and phosphorus, may be necessary in such patients.

The unique interactions of vitamin D with the vitamin D receptors have been a focus of research and have led to the development of vitamin D analogs, which vary in their affinity for these receptors and result in less hypercalcemia while retaining the positive physiologic actions on bone and parathyroid tissue. Paricalcitol and doxercalciferol are D_2 compounds that effectively lower PTH.[101] Paricalcitol differs from calcitriol by the absence of the exocyclic carbon 19 and the fact that it is a vitamin D_2 derivative. Doxercalciferol is a prohormone that needs to be hydroxylated in the liver to 1,25-dihydroxyvitamin D_2. These agents are available in an IV formulation for use in patients with stage 5 CKD and in oral forms that are approved for use in those with stage 3 to 5 CKD.

Pharmacokinetics. Calcitriol can be administered orally as well as by IV injection. Oral absorption occurs rapidly; therefore oral and IV therapies are both reasonable options for treatment of CKD-MBD. When paricalcitol is administered IV, its half-life is similar to that of calcitriol (up to 30 hours). The half-life of paricalcitol after oral administration is 17 to 20 hours in patients with stage 3 and 4 CKD.[102] Doxercalciferol has a slightly prolonged half-life of 45 hours.[103]

Efficacy. Administration of calcitriol by either the oral or the IV route may be based on conventional dosing (usually 0.25–0.5 mcg/day) or pulse dosing (0.5–2 mcg two to three times per week). Logistically, IV dosing is more practical in hemodialysis patients, whereas oral therapy is more practical for nondialysis CKD and peritoneal dialysis patients. Conventional daily oral doses of calcitriol may be more frequently associated with hypercalcemia and hyperphosphatemia, because vitamin D receptors are located in intestinal mucosa where direct stimulation can occur.

Although hypercalcemia is less likely with the newer analogs (paricalcitol and doxercalciferol), elevated calcium concentrations have been observed with these agents in patients with ESRD. However, some of these cases were associated with excessive dosing of these agents and oversuppression of PTH, a condition more likely to promote hypercalcemia. When administered at doses 10 times that of calcitriol and at a dose equivalent to doxercalciferol, paricalcitol has been less frequently associated with hypercalcemia in animal studies and in human trials.[104,105] Intestinal calcium absorption was 14% lower in paricalcitol-treated hemodialysis patients compared with those treated with calcitriol.[106] Doxercalciferol and paricalcitol have also been evaluated in patients with stages 3 and 4 CKD. They are effective in reducing PTH to target levels; however, differences in the magnitude of elevations of calcium and phosphorus have not been directly compared in this population.[107,108]

Although comparisons between vitamin D analogs are relatively limited the incidence of hyperphosphatemia with paricalcitol was lower than with doxercalciferol when administered at high doses to hemodialysis patients.[105] A more rapid suppression of PTH was also observed in paricalcitol-treated patients compared to those who received calcitriol. The more clinically significant finding from this study was the decrease in incidence of hypercalcemia and elevated Ca × P in the paricalcitol-treated patients.[109] Nontraditional effects of vitamin D, including a potential survival benefit, have also been reported.[101] An improvement in 3-year survival in a large dialysis population receiving paricalcitol was observed compared with a

TABLE 53-9 Available Vitamin D Agents

Generic Name	Trade Name	Form of Vitamin D	Dosage Range	Dosage Forms	Frequency of Administration
Vitamin D precursor					
Ergocalciferol[a]	Vitamin D_2	D_2	400–50,000 IU	PO	Daily (doses of 400–2000 IU)
Cholecalciferol[a]	Vitamin D_3	D_3			Weekly or monthly for higher doses (50,000 IU)
Active vitamin D					
Calcitriol	Calcijex		0.5–5 mcg	IV	Three times per week
	Rocaltrol		0.25–5 mcg	PO	Daily, every other day, or three times per week
Vitamin D analogs					
Paricalcitol	Zemplar		1–4 mcg	PO	Daily or three times per week
			2.5–15 mcg	IV	Three times per week
Doxercalciferol	Hectorol		5–20 mcg	PO	Daily or three times per week
			2–8 mcg	IV	Three times per week

[a]Multiple preparations are available that are not listed.

historic cohort that received calcitriol.[110] This survival advantage was also observed for hemodialysis patients who received vitamin D (either calcitriol or paricalcitol) compared with no vitamin D and was independent of calcium, phosphorus, and PTH.[111] The relationship between all available vitamin D agents (calcitriol, doxercalciferol, and paricalcitol) and mortality was further evaluated in a retrospective analysis of more than 7,700 hemodialysis patients.[112] After a median follow-up of 37 weeks, all-cause mortality and atherosclerotic cardiovascular mortality were similar for doxercalciferol- and paricalcitol-treated patients and similar to the calcitriol-treated patients when adjusted for laboratory values (e.g., calcium, PTH, albumin, phosphorus) and standardized mortality for the dialysis clinics included in this study. Vitamin D therapy, regardless of agent, was associated with lower mortality. It must be noted that these are observational studies and that prospective, randomized, controlled trials are required to better understand survival benefits associated with vitamin D therapy. Antiproteinuric effects of paricalcitol have also been reported in patients with stages 3 and 4 CKD.[113] These findings are of interest when considering other potential effects of vitamin D beyond suppression of PTH.

Adverse Effects. Although all agents are effective in suppressing PTH levels, they differ in the degree to which they cause other metabolic abnormalities. Adverse effects of note with vitamin D therapy in patients treated for CKD-MBD include hypercalcemia and hyperphosphatemia. Differences in calcitriol and vitamin D analogs have been demonstrated in animal studies and in clinical trials evaluating their effect on reduction of PTH while minimizing the risk of these adverse consequences.[105,106]

Drug–Drug and Drug–Food Interactions. Cholestyramine may reduce the absorption of orally administered calcitriol and doxercalciferol. In vitro data suggest that paricalcitol is metabolized by the hepatic enzyme CYP3A4 and has the potential to interact with other agents that are metabolized by this enzyme. When ketoconazole, a CYP3A4 inhibitor, was given concomitantly, paricalcitol serum concentrations doubled.[114] Caution is also advised when CYP3A4 inhibitors are given to those receiving doxercalciferol. No other significant interactions have been reported.

Dosing and Administration. Recommendations for vitamin D therapy differ based on the stage of CKD. Because deficiency in the vitamin D precursor, 25-hydroxyvitamin D, is common in patients with CKD, K/DOQI guidelines recommend measuring 25-hydroxyvitamin D levels in patients with stage 3 or 4 CKD who have PTH values above the upper recommended ranges (see Table 53–4). If the 25-hydryoxyvitamin D level is less than 30 ng/mL (75 nmol/L), a vitamin D precursor (e.g., ergocalciferol or cholecalciferol) is recommended. The dose and duration of treatment are dependent on the severity of the deficiency. To prevent vitamin D insufficiency, doses of 600 to 800 units per day of ergocalciferol are recommended. Calcitriol, doxercalciferol, or paricalcitol should be administered orally when PTH remains elevated despite the achievement of adequate 25-hydroxyvitamin D levels.

Initial oral doses of vitamin D recommended in patients with stage 3 or 4 CKD are 0.25 mcg calcitriol, 1 mcg doxercalciferol, or 1 mcg paricalcitol administered daily.[115] For paricalcitol the recommended daily dose is 2 mcg if the PTH is greater than 500 pg/mL (500 ng/L). If these agents are administered intermittently (generally three times per week), the recommended initial oral dose is twice the daily dose. Higher starting doses may be required based on the severity of CKD-MBD. Prior to starting therapy the serum calcium and phosphorus should be within the normal range to minimize the risk of hypercalcemia and an elevated Ca × P. In patients with ESRD there is a clearly defined role for treatment with active vitamin D or a vitamin D analog because the conversion of precursors to active vitamin D is impaired. The active vitamin D agents available in the United States vary markedly with regard to the oral and IV dosage regimens that are recommended for CKD patients (Table 53–9). Serum calcium and Ca × P should be monitored regularly while the patient is receiving therapy. Dose adjustments should be made every 2 to 4 weeks based on PTH concentrations.[22] For patients who need to be converted from calcitriol to paricalcitol, a dosing conversion ratio of 1:4 of IV calcitriol to paricalcitol has been proposed; however, some clinicians suggest a ratio of 1:3 to avoid oversuppression of PTH.

Calcimimetics

Pharmacology and Mechanism of Action. Cinacalcet hydrochloride (Sensipar) is a calcimimetic agent approved for treatment of secondary hyperparathyroidism in ESRD patients and for treatment of hypercalcemia in patients with parathyroid carcinoma. Cinacalcet is the first agent in this class to receive FDA approval. This compound acts on the calcium-sensing receptor on the surface of the chief cells of the parathyroid gland to mimic the effect of extracellular ionized calcium and increase the sensitivity of the calcium-sensing receptor to calcium, subsequently reducing PTH secretion. Cinacalcet does not increase intestinal calcium and phosphorus absorption. In fact, the reduction in PTH with cinacalcet is associated with a decrease in serum calcium.[116]

Pharmacokinetics. The maximum plasma concentration of cinacalcet is achieved in approximately 2 to 6 hours following oral administration. The half-life is approximately 30 to 40 hours. Cinacalcet has a large volume of distribution (approximately 1,000 L), and is 93% to 97% bound to plasma proteins, both characteristics indicating that removal by dialysis is negligible. Cinacalcet is metabolized by the liver, specifically by the cytochrome P450 isoenzymes CYP3A4, CYP2D6, and CYP1A2.[117]

Efficacy. In placebo-controlled clinical trials conducted in dialysis patients (predominantly those receiving hemodialysis) cinacalcet significantly decreased PTH and the Ca × P product within the 6-month study period, regardless of the severity of secondary hyperparathyroidism.[116] The starting dose of 30 mg per day was titrated every 3 or 4 weeks to a maximum dose of 180 mg per day to achieve the target PTH of ≤250 pg/mL (≤250 ng/L) and avoid hypocalcemia. Approximately 66% and 93% of patients in the clinical trials were receiving concurrent vitamin D and phosphate binders, respectively. If a patient experienced symptoms of hypocalcemia or had a serum calcium <8.4 mg/dL (<2.10 mmol/L), calcium supplements and/or calcium-based phosphate binders could be increased. If ineffective, the vitamin D dose could be increased. The median dose required to achieve the desired PTH by the end of the study period was 90 mg. This agent is not approved for use in patients with early stage CKD (stages 3–5 CKD not requiring dialysis) due to the risk of hypocalcemia. Because cinacalcet was approved after the K/DOQI guidelines on bone disease became available, the challenge to clinicians is in deciding how to most effectively use cinacalcet in conjunction with other therapies to manage CKD-MBD. KDIGO guidelines endorse the use of cinacalcet alone or in conjunction with vitamin D therapy to lower PTH in the dialysis population.[18] There are no studies evaluating the effect of cinacalcet on vascular calcification in humans.

Adverse Effects. The most frequently reported adverse events with cinacalcet were nausea and vomiting. Although nausea and vomiting occurred more frequently with cinacalcet, these events were generally transient, mild to moderate in nature, and infrequently led to withdrawal from clinical trials.[117]

Because cinacalcet lowers serum calcium and may cause hypocalcemia, this agent should not be started if the serum calcium is less than the lower limit of normal, approximately 8.4 mg/dL (2.10 mmol/L). Serum calcium should be measured within 1 week after initiation or following a dose adjustment of cinacalcet. Once the maintenance dose is established, serum calcium should be measured approximately monthly. Potential manifestations of hypocalcemia include paresthesia, myalgia, cramping, tetany, and convulsions.

Drug–Drug and Drug–Food Interactions. Because cinacalcet is metabolized by multiple hepatic enzymes there is potential for drug interactions. Cinacalcet is also a potent inhibitor of the enzyme CYP2D6. As a result, dose adjustments of concomitant medications that are predominantly metabolized by this enzyme and have a narrow therapeutic index, such as flecainide, thioridazine, vinblastine, and most tricyclic antidepressants (e.g., amitriptyline) may be required.[117]

Several agents commonly used in the CKD population have been evaluated for interactions with cinacalcet. Coadministration of calcium carbonate or sevelamer did not affect the pharmacokinetics of cinacalcet. Pantoprazole did not alter the pharmacokinetics of cinacalcet. This is an important finding because pantoprazole alters gastric pH, and the solubility of cinacalcet decreases as the gastric pH rises over 5.5. Coadministration of cinacalcet with warfarin also did not affect the pharmacokinetics of warfarin. Coadministration of cinacalcet and ketoconazole, a strong inhibitor of cytochrome P450 (CYP) 3A4, resulted in an increase in the area under the curve and maximum concentration of 2.3 and 2.2 times, respectively. Concurrent administration of cinacalcet with amitriptyline increased amitriptyline exposure and nortriptyline (active metabolite) exposure by approximately 20% in CYP2D6-extensive metabolizers.[117]

Food has been shown to increase absorption of cinacalcet by up to 81% compared with fasting; therefore this medication should be taken with meals to achieve the maximal effect.

Dosing and Administration. The recommended starting oral dose of cinacalcet is 30 mg once daily. The dose should be titrated every two to four weeks to a maximum dose of 180 mg once daily to achieve the desired PTH levels and to maintain near-normal serum calcium concentrations. Patients with hepatic disease may require lower doses, as studies have shown a decrease in metabolism of cinacalcet in this patient population. Cinacalcet is available as a film-coated tablet containing 30, 60, or 90 mg.

Pharmacoeconomic Considerations

Pharmacoeconomic considerations in the management of CKD-MBD and ROD include medication costs, the cost associated with laboratory monitoring, bone biopsies when indicated, and the medical expenditures associated with the management of calcifications and bone fractures. If the associated complications such as vascular and soft-tissue calcifications that may increase morbidity and hospitalizations can be significantly reduced, the additional medication costs may be of minimal consequence.

The pattern of vitamin D product use in U.S. dialysis units has been strongly influenced by Medicare reimbursement. Currently, IV vitamin D products are separately reimbursable expenses for dialysis programs. In fact, dialysis programs often generate significant profit from the IV administration of these agents. In contrast, oral administration of vitamin D is more convenient for patients with stage 3 or 4 CKD and the peritoneal dialysis population; however, these agents are not separately reimbursable. The fact that these agents must be purchased by the patient makes noncompliance with therapy an issue. The payment system for the hemodialysis population is all subject to change as the new "bundling" of payments for dialysis services, designed to reduce financial incentives for utilization of " unnecessary" dialysis services, is implemented in outpatient dialysis facilities (see Pharmacoeconomic Considerations for the anemia management section). In the bundling system currently proposed, the financial reimbursement a dialysis unit receives per dialysis session ($14 per dialysis treatment) would now also include costs of oral drugs such as phosphate binders and cinacalcet. There are concerns in the nephrology community about the effect the new system would have on treatment for CKD-MBD. Dialysis providers may advocate changing patients from more expensive, noncalcemic phosphate binders (e.g., sevelamer carbonate, and lanthanum carbonate) to less expensive calcium-containing binders. Calcitriol, which is more likely to cause hypercalcemia and hyperphosphatemia, may be used more in the ESRD population since both the IV and oral form are less expensive than paricalcitol and doxercalciferol. It is also anticipated that the use of cinacalcet may be reduced because of the cost of this oral calcimimetic. These changes in prescribing to reduce cost burden on dialysis facilities could potentially increase the incidence of hypercalcemia, calcifications, and morbidity in the ESRD population.

CHRONIC METABOLIC ACIDOSIS

Desired Outcome

The goals of therapy for patients with CKD are to normalize the pH of the blood (pH of approximately 7.35–7.45) and maintain the serum bicarbonate within the normal range (22–26 mEq/L [22–26 mmol/L]). In patients on hemodialysis, the goal of therapy is to maintain a predialysis or stabilized bicarbonate concentration at or above 22 mEq/L (22 mmol/L).[9] Metabolic acidosis appears to stimulate protein catabolism, which can contribute to a negative nitrogen balance and lower albumin concentrations. Lower serum bicarbonate levels in peritoneal dialysis patients have also been associated with a higher hospitalization rate and longer hospital stays.[9] Severe acidemia (blood pH <7.1–7.2) suppresses myocardial contractility, predisposes patients to cardiac arrhythmias, and may lead to a decrease in total peripheral vascular resistance and blood pressure, reduced hepatic

blood flow, and impaired oxygen delivery.[118] The prevention and treatment of severe metabolic acidosis in patients with kidney disease are also important to prevent the development of CKD-MBD since chronic metabolic acidosis has been shown to alter bone metabolism and decrease the effectiveness of vitamin D therapy.[22]

Nonpharmacologic Therapy

Therapy for metabolic acidosis requires pharmacologic intervention to correct the acidemia. Treatment of other underlying disorders that may be contributory is also warranted.

Pharmacologic Therapy

In patients with stage 4 or 5 CKD, the use of alkalinizing salts, such as sodium bicarbonate or citrate/citric acid preparations, is useful to replenish depleted body bicarbonate stores. Sodium bicarbonate tablets are manufactured in 325- and 650-mg strengths (a 650-mg tablet contains 7.6 mEq [7.6 mmol] sodium and 7.6 mEq [7.6 mmol] bicarbonate). Shohl solution and Bicitra contain 1 mEq/mL (1 mmol/mL) of sodium and the equivalent of 1 mEq/mL (1 mmol/mL) of bicarbonate as sodium citrate/citric acid. Citrate is metabolized in the liver to bicarbonate, and citric acid is metabolized to CO_2 and water. Polycitra, which contains potassium citrate (1 mEq/mL [1 mmol/mL] of sodium, 1 mEq/mL [1 mmol/mL] of potassium, and 2 mEq/mL [2 mmol/mL] of bicarbonate) should not be used in patients with severe CKD because of the risk of hyperkalemia.

The replacement dose of alkali (base) needed to restore the serum bicarbonate concentration to normal (24 mEq/L [24 mmol/L]) can be approximated by multiplying the volume of distribution of bicarbonate (0.5 L/kg) by the patient's body weight (in kilograms) and the patient's base deficit (difference between the patient's serum bicarbonate value and the normal value of 24 mEq/L [24 mmol/L]). The calculated amount of bicarbonate replacement therapy (in milliequivalents [or in mmols]) should be administered over several days to prevent volume overload from excessive sodium intake. After the serum bicarbonate has normalized, a maintenance regimen of bicarbonate to neutralize daily acid production may be all that is necessary (12 to 20 mEq/day [12 to 20 mmol/day] in divided doses). Doses are subsequently titrated to maintain normal plasma bicarbonate concentrations. Patients with renal tubular acidosis may require higher doses of alkalinizing agents (see Chap. 61). Fluid balance should be monitored carefully because of the sodium content of these agents. Citrate-containing solutions should not be used in combination with aluminum-containing compounds because they can enhance aluminum absorption and increase the risk of aluminum intoxication. Excessive doses of alkalinizing agents may cause metabolic alkalosis, as well as lethargy or cardiac depression secondary to a decrease in ionized serum calcium concentration. Gastrointestinal distress characterized by gastric distension and flatulence is relatively common with high doses of oral sodium bicarbonate. Patients with severe acidemia (serum bicarbonate <8 mEq/L [<8 mmol/L]; pH <7.2) will likely require IV therapy (see Chap. 61).

Metabolic acidosis in both adult and pediatric patients undergoing dialysis is usually managed by tailoring the patient's dialysis prescription. Increasing the concentration of bicarbonate (or acetate) in the dialysate to values above the serum bicarbonate concentration causes diffusion of the bicarbonate across the dialyzer and is an effective chronic treatment for metabolic acidosis in the dialysis population (see Chap. 54). Administration of oral bicarbonate salts may also be necessary for some dialysis patients.

Evaluation of Therapeutic Outcomes

Regular monitoring of serum electrolytes and arterial blood gases is necessary to determine the effectiveness of therapy. A gradual correction of serum bicarbonate is appropriate to avoid overcorrection and subsequent complications such as alkalosis and other electrolyte abnormalities (see Chap. 61). Laboratory measurement of serum bicarbonate is associated with several technical problems. Blood collection techniques, transportation, and assay methodology can affect the measured concentrations. Blood samples should not have contact with air, process delays should be avoided, and consistent analytical methods should be used with serial measurements to improve accuracy.[9]

CARDIOVASCULAR DISEASE

Specific recommendations regarding the management of cardiovascular disease in the ESRD population are included in K/DOQI guidelines. This includes recommendations for management of coronary artery disease, acute coronary syndromes, valvular heart disease, cardiomyopathy, dysrhythmias, cerebrovascular disease, and peripheral vascular disease. Differences in management of these disorders in dialysis patients compared with the general population are emphasized. Guidelines for management of cardiovascular risk factors are also included. Two of the most common medication amenable risk factors for cardiovascular disease in the CKD population—hypertension and hyperlipidemia—are discussed here.

Desired Outcome

Hypertension The goal blood pressure for cardiovascular risk reduction in patients with early-stage CKD is less than 130/80 mm Hg.[118] The target blood pressure in patients with ESRD is not well defined; however, the K/DOQI guidelines propose a predialysis blood pressure of less than 140/90 mm Hg and a postdialysis blood pressure of less than 130/80 mm Hg, although this recommendation is not based on data from prospective, controlled studies.[3] The targets may need to be individualized for patients who experience intradialytic hypotension (hypotension during the hemodialysis process). These goals can rarely be achieved using lifestyle modifications alone and aggressive antihypertensive therapy is often required.

Hyperlipidemia Based on strong evidence of risk reduction and the benefits of lipid-lowering therapy in the general population, the consensus is that CKD patients are among the highest-risk group for cardiovascular conditions (i.e., equivalent to that of patients with known coronary heart disease) and should be treated aggressively for dyslipidemia to an LDL cholesterol goal below 100 mg/dL (2.59 mmol/L).[41,119] The decision to lower LDL cholesterol to less than 70 mg/dL (1.81 mmol/L) based on more recent data in high-risk populations is a therapeutic option, although this approach is not supported by strong evidence from clinical trials in CKD. Table 53–10 lists the goals and suggested course of therapy based on the K/DOQI guidelines for patients with stage 5 CKD based on their lipid abnormality.

Nonpharmacologic Therapy

Hypertension Fluid intake should be restricted in patients with volume overload, particularly in patients on hemodialysis who are at risk for substantial fluid accumulation between dialysis sessions. Regular dietary counseling is critical to the success of nonpharmacologic interventions, given the large number of lifestyle changes typically required by CKD patients. Other lifestyle modifications, including regular exercise, weight loss, and smoking cessation, are also recommended but difficult to implement.

A primary nonpharmacologic intervention for management of hypertension in patients with ESRD is sodium restriction to approximately 2 g/day. In hemodialysis patients, achievement of an individual's "dry weight" is necessary to control blood pressure and may be done through dietary intervention, increased

TABLE 53-10 Management of Dyslipidemia in Patients with Chronic Kidney Disease[41]

Dyslipidemia	Goal	Initial Therapy	Modification in Therapy[a]	Alternative[a]
TG ≥500 mg/dL (≥5.56 mmol/L)	TG <500 mg/dL (<5.56 mmol/L)	TLC	TLC + fibrate or niacin	Fibrate or niacin
LDL 100–129 mg/dL (2.56–3.34 mmol/L)	LDL <100 mg/dL (<2.56 mmol/L)	TLC	TLC + low-dose statin	Bile acid sequestrant or niacin
LDL ≥130 mg/dL (≥3.36 mmol/L)	LDL <100 mg/dL (<2.56 mmol/L)	TLC + low-dose statin	TLC + maximum-dose statin	Bile acid sequestrant or niacin
TG ≥200 mg/dL (≥2.26 mmol/L) and non-HDL ≥130 mg/dL (≥3.36 mmol/L)	Non-HDL <130 mg/dL (<3.36 mmol/L)	TLC + low-dose statin	TLC + maximum-dose statin	Fibrate or niacin

HDL, high-density lipoprotein; LDL, low-density lipoprotein; Non-HDL, total cholesterol minus HDL cholesterol; TG, triglycerides; TLC, therapeutic lifestyle changes.
[a]Dosing of selected agents by class: fibrate (gemfibrozil 600 mg twice a day); niacin (1.5–3 g/day of immediate-release product); statin (simvastatin 10–40 mg/day if glomerular filtration rate [GFR] <30 mL/min [<0.50 mL/s], 20–80 mg/day if GFR >30 mL/min [>0.50 mL/s]); bile acid sequestrant (cholestyramine 4–16 g/day). See Chapter 28 for more complete dosing information.

ultrafiltration, and longer dialysis sessions (see Chap. 54). Aggressive ultrafiltration in hemodialysis patients has shown beneficial effects of lowering blood pressure and decreasing left ventricular mass index. Prolonged hemodialysis also better maintains normal blood pressure, improves survival, and reduces the need for antihypertensive medications; however, the majority of hemodialysis programs in the United States use shorter dialysis sessions (3- to 4-hour sessions three times per week).[3]

Hyperlipidemia In patients with elevated triglyceride levels (≥500 mg/dL [≥5.65 mmol/L]) and/or LDL between 100 and 129 mg/dL (2.56–3.34 mmol/L), lifestyle changes without pharmacologic therapy are recommended as initial therapy (see Chap. 28). Unfortunately, most patients with CKD have already been advised to adhere to difficult dietary regimens, which may include protein, phosphorus, sodium, potassium, and fluid restrictions. Thus, although diet therapy is a reasonable first-step approach, it may not be successful in many patients with CKD because of noncompliance. A dietitian who is well versed in the management of kidney disease should be consulted.

Pharmacologic Therapy

Hypertension Most patients with hypertension and advanced CKD (GFR <30 mL/min/1.73 m^2 [<0.29 mL/s/m^2]) require three or more antihypertensive agents to achieve target blood pressure.[118] Blood pressure reductions can be achieved with agents in all antihypertensive classes, although there is a preference for agents that inhibit the renin–angiotensin system, and choice should be guided by the individual patient's concomitant disease states.

Diuretic therapy is beneficial for management of blood pressure in patients with early CKD; however, thiazide diuretics are not generally effective in patients with a GFR of <30 mL/min (<0.50 mL/s). Loop diuretics can be used throughout all stages of CKD; however, patients with ESRD who have minimal to no residual kidney function will often not respond to these agents.

ACEIs or angiotensin receptor blockers are the preferred agents for patients with progressive CKD and proteinuria. They are also preferred in certain patients with ESRD because of their potential benefits including regression of LVH, reduction in sympathetic nerve activity and pulse-wave velocity, improvement in endothelial function, and reduced oxidative stress.[3] Lower initial doses of these agents may be necessary because the elimination half-lives of the parent compound (captopril and lisinopril) or active metabolite (enalapril, benazepril, and ramipril) are prolonged in ESRD patients. Available angiotensin receptor blockers do not require dosage adjustment for decreased kidney function, and they are not effectively removed by hemodialysis.

Calcium channel blockers that selectively lower systemic vascular resistance also appear to be effective in the treatment of hypertension in patients with ESRD and are associated with decreased total and cardiovascular mortality.[3] β-Blockers may be particularly useful in hypertensive CKD patients given the beneficial effects after myocardial infarction. Agents such as esmolol, timolol, pindolol, metoprolol, and labetalol, which are metabolized and not significantly removed by dialysis, may be easier to dose titrate than agents that are both dialyzable and extensively eliminated unchanged by the kidney (e.g., acebutolol, atenolol, bisoprolol, and nadolol). Agents requiring less-frequent dosing may be used to improve patient compliance.

Use of other antihypertensive agents in the patient with CKD should be based on recommendations in the general population (see Chap. 19). In the ESRD population, agents that act on the sympathetic nervous system, such as prazosin, terazosin, doxazosin, clonidine, guanabenz, and guanfacine, may be required in patients who are unresponsive to ACEIs, calcium channel blockers, or β-blocker therapy, and used in conjunction with adequate dialysis. Central α_2-agonists such as clonidine appear to be the safest of these agents; however, adverse effects, such as dry mouth, may lead to extra fluid consumption in some patients. Postsynaptic α-blockers (e.g., prazosin) are associated with postural hypotension following hemodialysis. Guanethidine and methyldopa should be avoided because of potential complications, including severe postural hypotension, severe dialysis-related hypotension, and impotence. The addition of vasodilators such as minoxidil may prove useful in patients resistant to combinations of the previously mentioned agents.

Based on claims data from the USRDS approximately 75% of stage 3 to 5 CKD patients with hypertension (excluding the ESRD population) received an ACEI or angiotensin receptor blocker within a year after diagnosis of CKD. The data also indicated that β-blockers and nondihydropyridine calcium channel blockers were used in approximately 50% and 40% of CKD patients, respectively. Loop diuretic use was reported in approximately 40% of stage 3 to 5 CKD patients and thiazide-like diuretics were prescribed for approximately 35%.[2]

Hyperlipidemia Management of dyslipidemia in patients with CKD is based on the report from the National Cholesterol Education Program and the K/DOQI guidelines for dyslipidemia in patients with CKD.[41,119] If lifestyle changes are not effective in achieving goal triglyceride and LDL levels after a few months, drug therapy is warranted (see Table 53–10 and Chap. 28). Drug therapy is also recommended for those with more extreme elevations in LDL (≥130 mg/dL [≥3.36 mmol/L]).

Drug classes that may prove useful in treatment of lipid disorders include 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (statins), bile acid sequestrants, nicotinic acid, and fibric acids (gemfibrozil and clofibrate). Statins are the most effective drugs for lowering LDL and total cholesterol in patients with kidney disease (with or without nephrotic syndrome) and generally should be regarded as the drugs of first choice, keeping in mind the controversies in the ESRD population (see below). Drug therapy for hypertriglyceridemia includes a fibrate or nicotinic acid; in general, fibrates are better tolerated. Patients receiving sevelamer as a phosphate binder may also benefit from its cholesterol-lowering effects.

Several potential drug interactions and/or adverse effects have been observed in those CKD patients receiving antilipemic therapy. The nonselective binding activity of bile acid sequestrants may reduce absorption of corticosteroids, digoxin, thiazide diuretics, warfarin, and other commonly used medications. Myositis and myalgia, along with increased serum creatine phosphokinase (CPK), may occur in ESRD patients who use clofibrate. Determining the optimal dose of clofibrate in this patient population is difficult as plasma protein-binding changes markedly affect free concentrations of the active metabolite clofibric acid, which has a prolonged half-life in patients with stage 5 CKD. Gemfibrozil may be a safer alternative, as the half-life is not altered with kidney dysfunction. Lower doses of 300 mg twice a day with close monitoring of CPK are recommended by some clinicians, based on an association of standard dose therapy with increases in CPK concentrations in dialysis patients.

Although statins are remarkably free of adverse effects in otherwise healthy subjects, one should be cognizant of the potential myotoxic effects of these drugs, especially when administered with interacting agents, such as azole antibiotics, cyclosporine, gemfibrozil, and niacin, and in the presence of hepatic disease.[119] There is increased risk of rhabdomyolysis with combined fibrate and statin therapy in patients with CKD, and diligent monitoring by prescribers and patients is necessary. Dose reductions are warranted for lovastatin and rosuvastatin in stage 4 CKD and with simvastatin in ESRD patients because of their reduced renal elimination.[120]

Statins in Early-Stage CKD. Statins are effective agents in patients with early-stage CKD, although there is little documented clinical trial data.[3] Atorvastatin therapy targeted to achieve an LDL of 80 mg/dL (2.07 mmol/L) or a maximum dose of 80 mg per day decreased cardiovascular risk in individuals with coronary heart disease and stage 3 CKD.[121] This effect was similar to that achieved in individuals without CKD. These results are similar to those from the Treating to New Targets trial, which evaluated atorvastatin (80 mg vs 10 mg per day) on cardiovascular events in patients with (n = 3,107) and without (n = 6,549) CKD.[122] Atorvastatin 80 mg reduced the relative risk of major cardiovascular events by 32% in patients with CKD over the median follow-up period of 5 years. Thus statin therapy clearly can reduce cardiovascular risk for patients with stage 3 CKD. Evidence of these benefits for those with stage 4 CKD, however, is lacking.

Statins in the ESRD Population. Data on statin use in the ESRD population are not consistently favorable as they are in early CKD. Although observational studies in hemodialysis patients receiving statins indicated a significant benefit: 31% relative risk reduction in overall mortality and a 23% reduction in cardiac causes of death,[123] the findings from prospective studies have not been encouraging.[124,125] Results from a 4-year study evaluating the effect of atorvastatin therapy on cardiac mortality in more than 1,200 hemodialysis patients with type 2 diabetes showed no significant benefit in the composite end point compared with the placebo group.[124] In fact, there was a significantly greater relative risk of fatal stroke in the atorvastatin-treated patients. These findings do not support initiation of statin therapy in ESRD patients, especially those with type 2 diabetes. The AURORA trial assessed the impact of rosuvastatin 10 mg daily or placebo on the primary end points of death from cardiovascular causes, nonfatal MI, or nonfatal stroke. Despite a 43% reduction in cholesterol in the rosuvastatin group there was no difference in the primary end points.[125] It is evident from these trials that information from the general population regarding statin therapy cannot be directly extrapolated to the ESRD population. Results from an ongoing trial known as the Study of Heart and Renal Protection (SHARP) trial will provide additional information on the use of the combination of simvastatin and ezetimibe both in those with early-stage CKD as well as in hemodialysis patients.[126]

CLINICAL CONTROVERSY

While observational studies have reported decreased mortality associated with statin use in the dialysis population, this has not been demonstrated in prospective trials (4D and AURORA trials). Critics of these prospective trials argue that these trials included patients with preexisting cardiovascular disease (e.g., history of MI) and speculate whether a study designed for primary prevention of cardiovascular events would have yielded positive results. There is also the argument that LDL cholesterol levels in the populations studied were relatively low and the effect of statins in individuals with higher LDL cholesterol levels (above 150 mg/dL [3.88 mmol/L]) was not adequately studied. For these reasons some practitioners support use of statins for primary prevention of cardiovascular events in the dialysis population and for individuals with LDL cholesterol levels well above 150 mg/dL (3.88 mmol/L).

Pharmacoeconomic Considerations

Hypertension Compliance and economic factors must be considered in the selection of antihypertensive therapy for CKD patients. Patients with ESRD are prescribed a median of eight medications.[32] Choosing agents that can be administered once or twice daily may improve patient compliance. In addition, there are now many options within some antihypertensive classes such as calcium channel blockers, ACEIs, angiotensin receptor blockers, and β-blockers, which allow for less-frequent dosing. In most cases, no clear therapeutic advantage has been demonstrated with any particular agent within a class. Therefore, selecting the least costly agent that can be administered once or twice daily is reasonable.

A meta-analysis of studies done in the hemodialysis population evaluating the effect of blood pressure lowering on cardiovascular outcomes showed that blood pressure lowering was associated with a decreased risk of cardiovascular events and all-cause and cardiovascular mortality.[127] As more information becomes available from studies evaluating the effects of long-term therapy of hypertension on cardiovascular events in patients with CKD, cost benefits from potentially decreasing the occurrence of such events and their comorbidities may be quantified.

Hyperlipidemia Statin therapy for treatment of dyslipidemias has been shown to be cost-effective in patients at high risk for coronary heart disease. Although this has not specifically been evaluated in patients with CKD, this population is considered in the highest-risk group for coronary heart disease and cardiovascular events. It may be reasonable, at least in theory, to extrapolate this information on the cost benefits of therapy to the CKD population, although findings from the trials in the ESRD population contradict this rationale.

Evaluation of Therapeutic Outcomes

Hypertension Blood pressure monitoring to determine the effectiveness of therapy should be done at each clinic visit, particularly following initiation of therapy (nonpharmacologic or pharmacologic), and at home when feasible. Patients on hemodialysis should have blood pressure measured before, during, and after dialysis to determine the effect of changes in their volume status on blood pressure. Some hemodialysis patients experience a paradoxical rise in blood pressure during dialysis. In these cases, the effect of dialysis

on removal of antihypertensive agents and the dosing times relative to the dialysis procedure need to be evaluated. Similarly, patients may need to adjust the time of administration of antihypertensive therapy relative to the dialysis session if intradialytic hypotension occurs. Such decisions should be based on the pharmacokinetic profile of the antihypertensive agent in patients with ESRD. Chapter 19 discusses more specifics of monitoring blood pressure and associated complications.

Hyperlipidemia Patients should have their lipid profile reassessed 2 to 3 months following a change in treatment and at least annually thereafter.[41] Periodic evaluations of cardiovascular performance, as described in Chapters 17 and 28, are also warranted.

OTHER COMPLICATIONS

Nutritional Status

Protein-energy malnutrition is very common among patients with advanced CKD (stages 4 and 5).[9] Causes of malnutrition in these patients include inadequate food intake secondary to anorexia, altered taste sensation, and the unpalatability of prescribed diets. Other factors in the ESRD population, such as the effect of the dialysis procedure on removal of nutrients, hypercatabolism induced by other inflammatory conditions, and blood loss are also contributory. Protein restriction as an intervention to potentially delay progression of kidney disease in patients with stage 3 or 4 CKD may also lead to protein malnutrition by the time a patient reaches ESRD; therefore the risks versus the benefits of this intervention must be considered on an individual basis (see Chap. 52) as hypoalbuminemia and malnutrition have a strong association with mortality in chronic dialysis patients.

Patients with ESRD have increased nutritional needs relative to the general population, based on the effect of the disease state and the dialysis procedure on nutritional status. The recommended dietary protein intake in chronic hemodialysis patients is 1.2 g/kg body weight per day.[9] The recommended intake for chronic peritoneal dialysis patients is at least 1.2 to 1.3 g/kg body weight per day, based on the increased protein loss that occurs with this dialysis modality. Protein requirements are higher in patients who are acutely ill (see Chap. 149). The recommended total daily energy intake in both hemodialysis and peritoneal dialysis patients is 35 kcal/kg (147 kJ/kg) body weight per day. For peritoneal dialysis patients, this includes intake from both diet and the glucose absorbed from peritoneal dialysate. For patients older than 60 years of age this criterion differs, because increasing age is generally associated with reduced physical activity and lean body mass. Daily energy intake for these patients is 30 to 35 kcal/kg (126–147 kJ/kg) body weight per day. Nutritional support should be considered for those patients who cannot achieve these goals with oral intake alone. Another option for nutritional supplementation in patients on hemodialysis includes interdialytic parenteral nutrition (see Chap. 151).

Vitamin requirements for ESRD patients receiving dialysis differ from those of a healthy person because of dietary modifications, kidney dysfunction, and dialysis therapy. The plasma concentrations of vitamins A and E are elevated in ESRD, whereas those of the water-soluble vitamins (B_1, B_2, B_6, B_{12}, niacin, pantothenic acid, folic acid, biotin, and vitamin C) tend to be low in large part because many are dialyzable. The goal for vitamin supplementation should be to prevent subclinical and frank deficiency and to avoid pathology from overdosage. Special vitamin supplements have been formulated for the dialysis population, which primarily include B vitamins with C and folic acid.

Supplementation with l-carnitine has been advocated for its potential benefits in patients with ESRD, including management of hypertriglyceridemia, hypercholesterolemia, and anemia.[128] Although some of these benefits have been demonstrated, the evidence does not strongly support routine supplementation. Cost and the addition of yet another medication to the already complex regimen prescribed for many of these patients also mitigate against the routine use of this agent.

Uremic Bleeding

Bleeding complications in patients with CKD are usually mild but can result in major hemorrhagic events. The primary mechanisms underlying the hemostatic problem are platelet biochemical abnormalities and alterations in platelet–vessel wall interactions. Decreased platelet aggregation and adhesiveness have been shown in a number of studies in ESRD patients.[129] Additionally, there is a decreased plasma concentration and defective binding of the large multimer of von Willebrand factor which results in abnormal platelet–blood vessel wall interactions. Patients on hemodialysis are at even greater risk of bleeding, not only because of the hemodialysis process itself but from administration of other medications. Heparin is frequently administered during dialysis procedures to prevent clotting during dialysis. Patients who are at high risk for bleeding may require alternative anticoagulation procedures rather than traditional hemodialysis with systemic heparinization. In addition, dialysis patients often receive systemic anticoagulation (warfarin) or antiplatelet therapy (aspirin or clopidogrel) for prevention of access clotting or other cardiovascular disorders. This complication is discussed in additional detail in Chapter 54.

CONCLUSIONS

The number of patients with and at risk for CKD is increasing, with a substantial rise in the population with stage 5 CKD expected in the next decade. Although efforts to delay progression of CKD are paramount, measures to diagnose and manage the associated secondary complications and comorbid conditions early in the course of the disease are also essential. Common complications of stages 4 and 5 CKD include anemia, CKD-MBD and renal osteodystrophy, fluid and electrolyte abnormalities, metabolic acidosis, and malnutrition. Cardiovascular complications are also prevalent in the population with CKD, and are the leading cause of mortality in patients with stage 5 disease. Patient education plays a critical role in the appropriate management of CKD and related complications.

A multidisciplinary team structure is a rational approach to providing this education and effectively designing and implementing the required extensive nonpharmacologic and pharmacologic interventions. Pharmacists are among the healthcare providers who contribute substantially to this team as shown by their activities in identifying and resolving drug-related problems, improving patient adherence with drug therapy, and providing more cost-effective medication use in dialysis facilities.[42,130] There are many opportunities for pharmacists to become involved in both the outpatient dialysis or ambulatory care settings as well as the inpatient environment to improve the management of patients with CKD and the associated complications.

ABBREVIATIONS

ACEI: Angiotensin-converting enzyme inhibitor

ABPM: Ambulatory blood pressure monitoring

AIDS: Acquired immunodeficiency syndrome

ARIC: Atherosclerosis Risk in Communities study

Ca × P: Calcium phosphorus product; serum calcium multiplied by serum phosphorus

CPK: Creatine phosphokinase
CPMs: Clinical performance measures
CMS: Centers for Medicare and Medicaid Services
CKD: Chronic kidney disease
DRPs: Drug-related problems
eGFR: Estimated glomerular filtration rate
EBCT: Electron-beam computed tomography
ESA: Erythropoietic-stimulating agent
ESRD: End-stage renal disease
FE_K: Fractional excretion of potassium
FE_{Na}: Fractional excretion of sodium
GFR: Glomerular filtration rate
Hb: Hemoglobin
HCT: Hematocrit
HDL: High-density lipoprotein
HMG-CoA: 3-hydroxy-3-methylglutaryl coenzyme A (reductase)
KDIGO: Kidney Disease: Improving Global Outcomes
K/DOQI: Kidney Disease Outcomes Quality Initiative
LDL: Low-density lipoprotein
LVH: Left ventricular hypertrophy
MBD: Mineral and bone disorder
MTM: Medication therapy management
PRCA: Pure red cell aplasia
PTH: Parathyroid hormone
ROD: Renal osteodystrophy
SHARP: Study of Heart and Renal Protection
sHPT: Secondary hyperparathyroidism
TREAT: Trial to Reduce Cardiovascular Events with Aranesp Therapy
TSat: Transferrin saturation
USRDS: United States Renal Data System

CHAPTER 54

Hemodialysis and Peritoneal Dialysis

KEVIN M. SOWINSKI AND MARIANN D. CHURCHWELL

KEY CONCEPTS

1. The hemodialysis procedure involves the perfusion of blood and dialysate on opposite sides of a semipermeable membrane. Substances are removed from the blood by diffusion and convection. Excess plasma water is removed via ultrafiltration.
2. The native arteriovenous fistula is the preferred access for hemodialysis because of fewer complications and a longer survival rate. Venous catheters are plagued by complications such as infection and thrombosis and often deliver relatively poor blood flow rates.
3. Adequacy of hemodialysis can be assessed by the Kt/V and urea reduction ratio (URR). The National Kidney Foundation's Kidney Disease Outcomes Quality Initiative has set the minimum goal Kt/V at greater than 1.2 per treatment and the URR at greater than 65%. In practice, most patients on hemodialysis exceed this goal.
4. During hemodialysis, patients commonly experience hypotension and cramps. Other more serious complications include infection and thrombosis of the vascular access.
5. The peritoneal dialysis procedure involves the instillation of dialysate into the peritoneal cavity via a permanent peritoneal catheter. The peritoneal membrane lines the highly vascularized abdominal viscera and acts as the semipermeable membrane across which diffusion and ultrafiltration occur. Substances are removed from the blood across the peritoneum via diffusion and ultrafiltration. Excess plasma water is removed via ultrafiltration created by osmotic pressure generated by various dextrose or icodextrin concentrations.
6. Patients on peritoneal dialysis are required to instill and drain, manually or via automated systems, several liters of fresh dialysate each day. The more exchanges a patient completes each day, the greater the solute removal.
7. Patients on peritoneal dialysis are required to instill and drain, manually or via automated systems, several liters of fresh dialysate each day. The more exchanges a patient completes each day, the greater the solute removal.
8. Nasal carriage of *Staphylococcus* aureus is associated with an increased risk of catheter-related infections and peritonitis. Prophylaxis with intranasal mupirocin (twice a day for 5 days every month) or mupirocin (daily) at the exit site can effectively reduce S. aureus infections.

The three primary treatment options for patients with end-stage renal disease (ESRD) are hemodialysis (HD), peritoneal dialysis (PD), and kidney transplantation. The United States Renal Data System (USRDS) is the national system that "collects, analyzes, and distributes" data relating to patients with ESRD or stage 5 chronic kidney disease (CKD) in the U.S.[1] According to the 2009 USRDS, at the end of 2007, there were more than 527,000 patients in the United States with ESRD. Of these, 341,264 and 26,340 patients were being treated with HD and PD, respectively, and 151,502 had a functioning kidney transplant. In 2007, nearly 111,000 new patients started therapy for ESRD (dialysis or transplantation) and over 88,000 patients died. The vast majority of new dialysis patients are treated with HD. The number of patients treated with PD has decreased by over 7% since 2000.[1] Although the number of patients who have received a kidney transplant has risen steadily, transplantation has not kept pace with the growing prevalence of ESRD in the United States.

CHAPTER 55

Drug-Induced Kidney Disease

THOMAS D. NOLIN AND JONATHAN HIMMELFARB

KEY CONCEPTS

1. The initial diagnosis of drug-induced kidney disease typically involves detection of elevated serum creatinine and blood urea nitrogen, for which there is a temporal relationship between the toxicity and use of a potentially nephrotoxic drug.
2. Drug-induced kidney disease is best prevented by avoiding the use of potentially nephrotoxic agents for patients at increased risk for toxicity. However, when exposure to these drugs cannot be avoided, recognition of risk factors and specific techniques, such as hydration, may be used to reduce potential nephrotoxicity.
3. Acute tubular necrosis is the most common presentation of drug-induced kidney disease in hospitalized patients. The primary agents implicated are aminoglycosides, radiocontrast media, cisplatin, amphotericin B, and osmotically active agents.
4. Angiotensin-converting enzyme inhibitors and nonsteroidal antiinflammatory drugs are associated with hemodynamically-mediated kidney injury, the pathogenesis of which is a decrease in glomerular capillary hydrostatic pressure.
5. Acute allergic interstitial nephritis is observed in up to 27% of kidney biopsies performed for hospitalized patients with unexplained acute kidney injury. Clinical manifestations of allergic interstitial nephritis typically present approximately 14 days after initiation of therapy and include fever, maculopapular rash, eosinophilia, arthralgia, often with pyuria, hematuria, proteinuria, and oliguria.

Numerous diagnostic and therapeutic agents have been associated with the development of drug-induced kidney disease (DIKD) or nephrotoxicity. It is a relatively common complication with variable presentations depending on the drug and clinical setting, inpatient or outpatient. Manifestations of DIKD include acid–base abnormalities, electrolyte imbalances, urine sediment abnormalities, proteinuria, pyuria, and/or hematuria.[1] However, the most common manifestation of DIKD is a decline in the glomerular filtration rate (GFR), which results in a rise in serum creatinine (S_{cr}) and blood urea nitrogen (BUN) and several other indicators of acute and chronic kidney injury (see Chaps. 50 and 51). Initial diagnosis of DIKD is often delayed as it typically is based on the detection of elevated S_{cr} and BUN, for which there is a temporal relationship between the kidney injury and exposure to the potentially nephrotoxic drug. This is consistent with classic qualitative definitions of acute renal failure, which have relied on either an abrupt increase in S_{cr} or an abrupt decline in urine output (see Chaps. 50 and 51).[2] The clinical use of numerous definitions of acute renal failure and nephrotoxicity based on quantitative changes in the S_{cr} concentration and other clinical end points made it extraordinarily difficult to ascertain their true incidence.[3] Relatively new diagnostic criteria based on a combination of physiologic measurements (e.g., S_{cr} and urine output) have been recently introduced and are now being incorporated into clinical practice and research.[4–6] This has resulted in replacement of the term *acute renal failure* with *acute kidney injury* (AKI) and will likely lead to epidemiologic data about DIKD that are more accurate in the future.

Nephrotoxicity is often reversible if one discontinues the use of the offending agent, but in some cases there may still be an AKI and progression to stage 5 chronic kidney disease (CKD) which is also termed *end-stage renal disease* (ESRD). Currently, many different mechanisms are responsible for the pathogenesis of DIKD, and the introduction of new drugs with novel mechanisms of action provides the potential for the identification of new presentations of AKI and CKD. This chapter reviews the epidemiology, pathophysiology, risk factors, and basic principles of prevention of DIKD. Detailed discussions of these issues plus management strategies are presented for the most commonly used agents that have been associated with a moderate to high likelihood of DIKD.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

EPIDEMIOLOGY

The incidence and characteristics of outpatient or community-acquired DIKD are not well understood since mild toxicity is often unrecognized in this setting. However, the acquisition of data regarding the pharmacoepidemiology of these effects has become more important as care increasingly shifts to the outpatient setting. The incidence of community-based AKI that required dialysis was recently reported to be 29.5 per 100,000 person years and 522.4 per 100,000 person years for patients not requiring dialysis.[7] Although the incidence of drug-induced AKI was not specifically reported, earlier studies have implicated community-acquired DIKD in up to 20% of hospital admissions due to AKI.[8] Conversely, AKI has been reported in up to 7% of hospitalized patients,[9] and as many as 20% to 30% of critically ill patients may experience AKI during their hospitalization.[10,11] Drug-induced causes have been implicated in up to 60% of all cases of in-hospital AKI and as such are a recognized source of significant morbidity and mortality.[12] Although the incidence of in-hospital antibiotic-induced AKI alone

has been reported to be as high as 36%,[1] it appears to be declining, while cases of in-hospital AKI due to nonselective nonsteroidal antiinflammatory drugs (NSAIDs), angiotensin-converting enzyme inhibitors (ACEIs), chemotherapeutic agents, and antiviral drugs are increasing.[2]

CLINICAL PRESENTATION OF DRUG-INDUCED KIDNEY DISEASE

General

- The most common manifestation is a decline in GFR leading to a rise in S_{cr} and BUN.
- Alterations in renal tubular function without loss of glomerular filtration may be evident.

Symptoms

- Patients may complain of malaise, anorexia, vomiting, shortness of breath, or edema, particularly in the outpatient setting.

Signs

- Decreased urine output may be an early sign of toxicity, particularly with radiographic contrast media, NSAIDs, and ACEIs, with progression to volume overload and hypertension.
- Proximal tubular injury: Metabolic acidosis with bicarbonaturia; glycosuria in the absence of hyperglycemia; and reductions in serum phosphate, uric acid, potassium, and magnesium due to increased urinary losses.
- Distal tubular injury: Polyuria from failure to maximally concentrate urine, metabolic acidosis from impaired urinary acidification, and hyperkalemia from impaired potassium excretion.

Laboratory Tests

- An abrupt (within 48 hours) reduction in kidney function defined as an absolute increase in S_{cr} of ≥0.3 mg/dL (27 μmol/L), a percentage increase in S_{cr} of ≥50% (1.5-fold from baseline), or a reduction in urine output (documented oliguria of less than 0.5 ml/kg per hour for more than 6 hours)],[13] when correlated temporally with the initiation of drug therapy may indicate drug-induced AKI.

Other Diagnostic Tests

- Urinary excretion of *N*-acetyl-*β*-D-glucosaminidase, *γ*-glutamyl transpeptidase, glutathione S-transferase, and interleukin (IL)-18 are markers of proximal tubular injury and have been used for the early detection of AKI in critically ill patients.
- Kidney injury molecule-1 (KIM-1) is expressed in the proximal tubule and is upregulated for patients with ischemic acute tubular necrosis, appearing in the urine within 12 hours after the ischemic insult.
- Neutrophil gelatinase-associated lipocalin (NGAL) protein may be detected in the urine within 3 hours of ischemic injury.

1 Because the most common manifestation of DIKD is a decline in GFR leading to a rise in S_{cr} and BUN, the onset of toxicity in hospitalized, acutely ill patients is most often recognized by routine laboratory monitoring. Decreased urine output may also be an early sign of toxicity, particularly with radiographic contrast media, NSAIDs, and ACEIs. In the outpatient setting, nephrotoxicity is often recognized by the development of symptoms such as malaise, anorexia, vomiting, volume overload (shortness of breath or edema), and hypertension. S_{cr} or BUN concentrations and urine collection for creatinine clearance may subsequently be measured to quantify the degree of decline in GFR. Marked intrasubject between-day variability of S_{cr} values have been noted (±20% for values within the normal range; see Chap. 50). Furthermore, they may be altered as the result of dietary changes and initiation of drug therapy, which may interfere with the assay procedure. Thus changes in S_{cr} or urine output consistent with the diagnostic criteria for AKI (see Chap. 51),[13] when correlated temporally with the initiation of drug therapy, are a common threshold for the identification of DIKD.

Nephrotoxicity may also be evidenced by primary alterations in renal tubular function without a corresponding loss of glomerular filtration (Table 55–1). In this setting, urinary enzymes and low-molecular-weight proteins may be used as earlier and more specific biomarkers of nephrotoxicity compared with S_{cr} and BUN, which are relatively insensitive markers of kidney injury.[14] S_{cr} and BUN are used as surrogates of kidney function, not injury per se, and typically significant kidney injury must have occured days before a rise in either is evident. Urinary excretion of kidney injury molecule-1 (KIM-1), N-acetyl-*β*-glucosaminidase, *γ*-glutamyl transpeptidase, glutathione *S*-transferase, neutrophil gelatinase-associated lipocalin (NGAL), and interleukin-18 are markers of proximal tubular injury and have been used for the early detection of acute kidney damage

TABLE 55-1 Drug-Induced Renal Structural–Functional Alterations and Examples

Tubular epithelial cell damage

Acute tubular necrosis
- Aminoglycoside antibiotics
- Radiographic contrast media
- Cisplatin, carboplatin
- Amphotericin B
- Cyclosporine, tacrolimus
- Adefovir, cidofovir, tenofovir
- Pentamidine
- Foscarnet
- Zoledronate

Osmotic nephrosis
- Mannitol
- Dextran
- Intravenous immunoglobulin

Hemodynamically-mediated kidney injury
- Angiotensin-converting enzyme inhibitors
- Angiotensin II receptor blockers
- Nonsteroidal anti-inflammatory drugs
- Cyclosporine, tacrolimus
- OKT3

Obstructive nephropathy

Intratubular obstruction
- Acyclovir
- Sulfonamides
- Indinavir
- Foscarnet
- Methotrexate

Nephrolithiasis
- Sulfonamides
- Triamterene
- Indinavir

Nephrocalcinosis
- Oral sodium phosphate solution

Glomerular disease
- Gold
- Lithium
- Nonsteroidal antiinflammatory drugs, cyclooxygenase-2 inhibitors
- Pamidronate

Tubulointerstitial disease

Acute allergic interstitial nephritis
- Penicillins
- Ciprofloxacin
- Nonsteroidal anti-inflammatory drugs, cyclooxygenase-2 inhibitors
- Proton pump inhibitors
- Loop diuretics

Chronic interstitial nephritis
- Cyclosporine
- Lithium
- Aristolochic acid

Papillary necrosis
- NSAIDs, combined phenacetin, aspirin, and caffeine analgesics

Renal vasculitis, thrombosis, and cholesterol emboli

Vasculitis and thrombosis
- Hydralazine
- Propylthiouracil
- Allopurinol
- Penicillamine
- Gemcitabine
- Mitomycin C
- Methamphetamines
- Cyclosporine, tacrolimus
- Adalimumab
- Bevacizumab

Cholesterol emboli
- Warfarin
- Thrombolytic agents

in several patient populations.[14–16] For example, the transmembrane protein KIM-1 is upregulated for patients with ischemic acute tubular necrosis, appearing in the urine within 12 hours after the ischemic insult.[16] Urinary *N*-acetylglucosamine (NAG) concentrations are a highly sensitive indicator of AKI and have been shown to detect AKI in critically ill patients up to 4 days prior to a rise in S_{cr} was observed.[16] Similarly, urinary NGAL is an early marker of AKI, preceding a rise in S_{cr} by up to 3 days. In the future, urinary biomarkers such as KIM-1, NAG, and NGAL may facilitate the earlier detection of kidney injury and diagnosis of nephrotoxicity and minimize the long-term consequences of this common drug-induced disorder.[14,16]

PRINCIPLES FOR PREVENTION OF DRUG-INDUCED NEPHROPATHY

2 The primary principle for prevention of DIKD is to avoid the use of nephrotoxic agents for patients at increased risk for toxicity. Therefore, an awareness of potentially nephrotoxic drugs and knowledge of risk factors that increase renal vulnerability is essential.[17] Exposure to these drugs often cannot be avoided, so several interventions have been proposed to reduce the potential for the development of nephrotoxicity, for example, adjustment of medication dosage regimens based on accurate estimates of renal function, and careful and adequate hydration to establish high urine flow rates.[12,18] Other preventative strategies are still theoretical and/or investigational and relate directly to the specific nephrotoxic mechanisms of a given drug. For example, cidofovir and adefovir are antiretroviral drugs that are actively transported by human organic anion transporter 1 (OAT1).[1,19] Competitive inhibition of OAT1-mediated transport with probenecid minimizes intracellular accumulation of cidofovir and adefovir in renal proximal tubule cells and reduces the likelihood of nephrotoxicity.[1,20]

Table 55–1 lists the several specific drug-induced renal structural–functional alterations that are responsible for the vast majority of cases of DIKD. This chapter discusses the pathophysiologic mechanisms responsible for the development of DIKD with these agents in detail, along with clinical presentation, prevention strategies, therapeutic management approaches, and relevant monitoring plans.

TUBULAR EPITHELIAL CELL DAMAGE

3 Drugs that lead to renal tubular epithelial cell damage typically do so via direct cellular toxicity or ischemia. Damage is most often localized in the proximal and distal tubular epithelia and is termed *acute tubular necrosis* (ATN) when cellular degeneration and sloughing from proximal and distal tubular basement membranes are observed.[21,22] This classically manifests as cellular debris-filled, muddy-brown, granular casts in the urinary sediment.[22,23] Specific indicators of proximal tubular injury include metabolic acidosis with bicarbonaturia; glycosuria in the absence of hyperglycemia; and reductions in serum phosphate, uric acid, potassium, and magnesium as a result of increased urinary losses. Indicators of distal tubular injury include polyuria from failure to maximally concentrate urine (i.e., nephrogenic diabetes insipidus), metabolic acidosis from impaired urinary acidification, and hyperkalemia from impaired potassium excretion.[1] ATN is the most common presentation of DIKD in the inpatient setting. The primary agents associated with this type of injury are aminoglycosides, radiocontrast media, cisplatin, amphotericin B, foscarnet, and osmotically active agents such as immunoglobulins, dextrans, and mannitol.[1,11,24,25]

ACUTE TUBULAR NECROSIS

Aminoglycoside Nephrotoxicity

Incidence Aminoglycoside antibiotic-associated nephrotoxicity has been reported to occur in between 10% and 25% of patients receiving a therapeutic course.[11,26,27] Critically ill patients appear to have a higher risk for nephrotoxicity with reported rates as high as 58%.[26] The large variance is in part a result of the use of different definitions of toxicity, variability between agents in the class, and the risk factors present in the study population.

Clinical Presentation Clinical evidence of aminoglycoside-associated nephrotoxicity is typically seen within 5 to 10 days after initiation of therapy and manifests as a gradual progressive rise in S_{cr} and BUN and decrease in creatinine clearance.[11] Patients usually present with nonoliguria, i.e., they maintain urine volumes greater than 500 mL/day and sometimes have microscopic hematuria and proteinuria.[11,25] Although renal magnesium wasting can occur (i.e., daily excretion of more than 10 to 30 mg), the risk of symptomatic hypomagnesemia is generally low. Full recovery of renal function is common if aminoglycoside therapy is discontinued immediately upon discovering signs of toxicity.[11] However, severe AKI may develop occasionally, and for these individuals renal replacement therapy may be required (see Chap. 51). The diagnosis of aminoglycoside-associated nephrotoxicity is often difficult, particularly in critically ill patients with multiple comorbidities and is confounded by other factors that are independently associated with the development of AKI.[26] For instance, concurrent dehydration, sepsis, hypotension, ischemia, and use of other nephrotoxic drugs frequently contribute to AKI in patients who are receiving aminoglycosides.[22]

Pathogenesis Aminoglycoside-associated ATN is primarily due to accumulation of high drug concentrations within proximal tubular epithelial cells, and subsequent generation of reactive oxygen species that produce mitochondrial injury, which leads to cellular apoptosis and necrosis.[17,25] This results in cell sloughing from proximal tubular basement membranes into the tubular lumen, which can result in tubular obstruction and back leakage of the glomerular filtrate across the damaged tubular epithelium. Toxicity is related to cationic charge of the drugs in this class, which facilitates their binding to negatively charged renal tubular epithelial membrane phospholipids in the proximal tubules, followed by intracellular transport and concentration in lysosomes. The number of cationic groups on the drug molecule appear to correlate with the degree of nephrotoxicity, which is consistent with the observation of higher rates of toxicity with neomycin versus gentamicin, followed by tobramycin, then amikacin.[1,11,17]

Risk Factors Multiple risk factors for aminoglycoside-associated nephrotoxicity have been identified: the aggressiveness of aminoglycoside dosing, synergistic toxicity as the result of combination drug therapy and preexisting clinical conditions of the patient (Table 55–2).[11,17,26]

Prevention Aminoglycoside-associated ATN may be prevented by careful and cautious selection of patients and the use of alternative antibiotics whenever possible and as soon as microbial sensitivities are known. Commonly used alternatives include fluoroquinolones (e.g., ciprofloxacin or levofloxacin) and third- or fourth-generation cephalosporins (e.g., ceftazidime or cefepime). When aminoglycosides are necessary, gentamicin, tobramycin, and amikacin are most commonly used, but therapy should be selected to optimize antimicrobial efficacy.[28] Furthermore, it is imperative to avoid volume depletion, limit the total aminoglycoside dose administered, and avoid concomitant therapy with other nephrotoxic drugs. Future therapeutic alternatives may include new aminoglycoside congeners that retain the desired bactericidal activity and yet are devoid

TABLE 55-2 Potential Risk Factors for Aminoglycoside Nephrotoxicity

A. Related to aminoglycoside dosing:
- Large total cumulative dose
- Prolonged therapy
- Trough concentration exceeding 2 mg/L[a]
- Recent previous aminoglycoside therapy

B. Related to synergistic nephrotoxicity. Aminoglycosides in combination with
- Cyclosporine
- Amphotericin B
- Vancomycin
- Diuretics
- Iodinated radiographic contrast agents
- Cisplatin
- NSAIDs

C. Related to predisposing conditions in the patient:
- Preexisting kidney disease
- Diabetes
- Increased age
- Poor nutrition
- Shock
- Gram-negative bacteremia
- Liver disease
- Hypoalbuminemia
- Obstructive jaundice
- Dehydration
- Hypotension
- Potassium or magnesium deficiencies

[a]The equivalent concentration in SI molar units are 4.3 μmol/L for tobramycin, 4.2 μmol/L for gentamicin, and 1.4 μmol/L for vancomycin.

of nephrotoxicity,[29] and may also include concurrent use of antioxidant compounds such as vitamin E and *N*-acetylcysteine.[30]

Prospective, individualized pharmacokinetic monitoring has been used for more than three decades, and its use has been associated with a decrease in the incidence of aminoglycoside-associated nephrotoxicity.[31] These studies, however, were often small and statistically underpowered. High-dose intermittent dosing of aminoglycosides, termed *once daily dosing*, used in combination with other antibiotics, has been intensively investigated as a practical cost-effective method to maintain antimicrobial efficacy while reducing AKI.[32] The reduction in incidence may be the result of limited proximal tubular aminoglycoside uptake during the transient, high-peak serum concentrations, and because of the presence of low aminoglycoside concentrations for a greater proportion of the dosing interval which facilitates excretion of the aminoglycoside.[28] Although greater clinical efficacy and reduced nephrotoxicity may be realized with once daily compared with standard dosing, seriously ill, immunocompromised, and elderly patients, as well as those with preexisting kidney disease, are not ideal candidates for this approach.[32]

Management Aminoglycoside use should be discontinued or the dosage regimen revised if AKI is evident [i.e., there is an S_{cr} increase of 0.5 mg/dL (44 μmol/L) or more that is not attributable to another cause]. Other nephrotoxic drugs should be discontinued if possible, and the patient should be maintained adequately hydrated and hemodynamically stable.[10] Short-term renal replacement therapy may be necessary, but ESRD has rarely been reported to be solely the result of aminoglycoside toxicity.

Radiographic Contrast Media Nephrotoxicity

Incidence The incidence of radiographic contrast media-induced nephrotoxicity (CIN) has declined over the last decade from approximately 15% to 7% of all patients receiving iodinated contrast; yet it remains the third leading cause of hospital-acquired AKI, accounting for up to 11% of cases.[33,34] The incidence varies depending on the population studied and presence of risk factors; rising from <2% for patients with normal renal function up to 50% for patients with a high risk, such as those with CKD or diabetes mellitus.[35,36] As the number of risk factors associated with CIN increases, there is a proportional increase in the incidence of nephrotoxicity and in short- and long-term mortality rates.[34,37] A 5.5-fold increased risk of death has been reported for patients who develop CIN compared with those who do not, with the highest mortality rates observed for patients who develop AKI and require renal replacement therapy.[34,37] In-hospital and 2-year mortality rates of 36% and 81%, respectively, have been reported for patients who develop CIN and require dialysis; an in-hospital mortality rate of only 7% was observed in those with nephrotoxicity not requiring dialysis.[34]

Clinical Presentation CIN is usually transient in nature, presenting most commonly as nonoliguria with kidney injury apparent within the first 24 to 48 hours after the administration of contrast. The S_{cr} concentration usually peaks between 3 and 5 days after exposure, with recovery after 7 to 10 days.[33,35,38] However, irreversible oliguric (urine volume <500 mL/day) AKI requiring dialysis has been reported in high-risk patients.[37] Urinalysis typically reveals tubular enzymuria with hyaline and granular casts but may also be completely void of casts. The urine sodium concentration and fractional excretion of sodium are frequently low, with the latter typically <1% (<0.01).[1]

Pathogenesis The primary mechanisms by which contrast media induces nephrotoxicity are renal ischemia and direct cellular toxicity.[34,35] Renal ischemia likely results from systemic hypotension and simultaneous acute vasoconstriction caused by disruption of normal prostaglandin synthesis and the release of adenosine, endothelin, and other renal vasoconstrictors. Subsequently, a 50% sustained reduction in renal blood flow that lasts for several hours immediately following contrast administration may be evident.[34] This reduced renal blood flow leads to increased concentrations of contrast in the renal tubules and exacerbates the direct cytotoxicity and ATN. The extent of cellular toxicity is directly related to the duration of tubular cell exposure to contrast. Thus, preservation of high urinary flow rates with adequate hydration before, during, and after contrast administration is vital to keep renal blood flow as high as reasonably possible to minimize tubular cell exposure to the contrast agent.[34,35] In humans, plasma osmolality is normally between 275 and 290 mOsm/kg (275 and 290 mmol/kg). Since low- and high-osmolar contrast agents are hyperosmolar to plasma [i.e., 600 to 800 mOsm/kg (600 to 800 mmol/kg) and ~2,000 mOsm/kg (~2,000 mmol/kg)] respectively, their use may result in osmotic diuresis, dehydration, renal ischemia, and increased blood viscosity caused by red blood cell aggregation. Oxidative stress has also been implicated in the development of ATN after contrast administration,[39] which may explain the possible benefit of the antioxidant *N*-acetylcysteine.[40–42]

Risk Factors Decreased renal blood flow exacerbates the ischemic and direct cytotoxic effects of contrast media on the renal tubules. Therefore, preexisting kidney disease, particularly in those with estimated GFR <60 mL/min/1.73 m^2 (<0.58 mL/s/m^2), is the most important risk factor present in up to 60% of patients who develop CIN.[34,35] Other patients' specific risk factors include conditions associated with decreased renal blood flow (i.e., congestive heart failure, dehydration/volume depletion, and hypotension), and patients with atherosclerosis and reduced effective circulating arterial blood volume appear to also have an elevated risk.[38,43] Diabetes is also a significant risk factor, likely due to coexisting kidney disease (diabetic nephropathy). The presence of multiple myeloma has traditionally been considered a relative contraindication for contrast use, but the risk appears to be associated with concomitant dehydration, kidney

disease, or hypercalcemia rather than the diagnosis itself.[35] Larger volumes or doses of contrast and use of low- and high-osmolar contrast agents are also independent predictors of CIN. Intraarterial administration of contrast confers greater risk than intravenous administration.[34] Lastly, concurrent use of nephrotoxins and drugs that alter renal hemodynamics such as NSAIDs and ACEIs also increases risk.[38] Risk factors are additive, and there is a proportional increase in the incidence of CIN and associated mortality as the number of risk factors increases.[34,37]

Prevention CIN can be anticipated in the majority of patients who are at risk; so the use of preventative procedures is justified for virtually all patients. Table 55–3 lists the recommended interventions for prevention of contrast nephrotoxicity. All patients scheduled to receive contrast media should be assessed for risk factors, and the risk-to-benefit ratio should be considered.[33–35,38,41,43,44] High-risk patients can be identified by evaluating medical history and indication for the contrast study, along with their most recent S_{cr} concentrations. Nephrotoxicity is best prevented in high-risk patients by using alternative imaging procedures (e.g., ultrasound, noncontrast magnetic resonance imaging, and nuclear medicine scans).[41] However, if contrast media must be used, the smallest adequate volume should be administered. If the ratio of the volume of contrast to be infused relative to the patient's creatinine clearance is ≥3.7 (≥222 if creatinine clearance is expressed in units of milliliters per second), the likelihood of nephrotoxicity is markedly increased.[45] Therefore, in general, the volume of contrast (in milliliters per second) administered should not be greater than twice the baseline estimated creatinine clearance.[34]

Low-osmolar (600 to 800 mOsm/kg; 600 to 800 mmol/kg) nonionic (iohexol and iopamidol) and ionic (ioxaglate) contrast agents may be used to prevent or minimize the incidence of nephrotoxicity. Standard hyperosmolar contrast media (e.g., low- and high-osmolar agent) are not reabsorbed in the kidney and cause osmotic diuresis, which contributes to the renal toxicity observed with these agents. Low-osmolar contrast agents have less than half the osmolality of high-osmolar (~2,000 mOsm/kg; ~2,000 mmol/kg) agents and are associated with less toxicity, especially when used for patients with preexisting kidney disease.[46] However, use of low-osmolar agents does not preclude the development of nephrotoxicity. Even low-osmolar agents are hyperosmolar to plasma, which is likely the reason they are associated with greater nephrotoxicity than the iso-osmolar nonionic contrast agent iodixanol.[47] Iodixanol has been shown to have the lowest risk for CIN for patients with CKD and diabetes.[34,46]

TABLE 55-3 Recommended Interventions for Prevention of Contrast Nephrotoxicity[33,34,42,48,50,52]

Intervention	Recommendation	Recommendation Grade[a]
Contrast	• Minimize contrast volume/dose	A-1
	• Use noniodinated contrast studies	A-2
	• Use low- or iso-osmolar contrast agents	A-2
Medications	• Avoid concurrent use of potentially nephrotoxic drugs, e.g., NSAIDs, aminoglycosides	A-2
Isotonic sodium chloride (0.9%)	• Initiate infusion 3–12 hours prior to contrast exposure and continue 6–24 hours postexposure • Infuse at 1–1.5 mL/kg/h adjusting postexposure as needed to maintain urine flow rate of ≥150 mL/h • Alternatively, in urgent cases, initiate infusion at 3 mL/kg/h, beginning 1 hour prior to contrast exposure, then continue at 1 mL/kg/h for 6 hours postexposure	A-1
Isotonic sodium bicarbonate [154 mEq/L (154 mmol/L)]	• Initiate and maintain infusion as per isotonic sodium chloride above • Alternatively, initiate infusion at 3 mL/kg/h, beginning 1 hour prior to contrast exposure, then continue at 1 mL/kg/h for 6 hours postexposure	B-2
N-acetylcysteine	• Administer 600–1,200 mg by mouth (PO) every 12 hours, 4 doses beginning prior to contrast exposure (i.e., 1 dose prior to exposure and 3 doses postexposure)	B-1

[a]Strength of recommendations: A, B, and C are good, moderate, and poor evidence to support recommendation, respectively. Quality of evidence: 1, evidence from more than 1 properly randomized, controlled trial; 2, evidence from more than 1 well-designed clinical trial with randomization, from cohort or case-controlled analytic studies or multiple time series, or dramatic results from uncontrolled experiments; 3 evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert communities.

CLINICAL CONTROVERSY

Some clinicians believe that low- or iso-osmolar contrast media should be used for virtually all patients at risk for toxicity. Others believe that the cost-to-benefit ratio of using low-osmolar contrast agents to prevent nephrotoxicity is questionable except for patients at high risk.

Volume expansion and correction of dehydration prior to contrast administration is a mainstay of preventive therapy.[41,48] Parenteral hydration with isotonic saline before and after contrast administration reduces the incidence of toxicity, particularly in high-risk patients, and is currently the most widely accepted preventative intervention.[35,48] Volume expansion may exert its beneficial effects through dilution of contrast media, prevention of renal vasoconstriction leading to ischemia, preservation of high urine flow rates, decreased tubular cell exposure to contrast, and avoidance of tubular obstruction.[48] Hydration with isotonic sodium bicarbonate has been shown to provide more protection than saline, perhaps by reducing the formation of pH-dependent oxygen free radicals,[49,50] but recent studies reported contradictory findings.[41,51] Larger, adequately powered studies are needed to confirm these findings and to demonstrate conclusively that bicarbonate based hydration is superior to saline.[48] The use of oral hydration regimens has also been proposed but also requires further study to clarify its role and is not currently recommended in lieu of parenteral hydration.[41,48]

N-acetylcysteine is a thiol-containing antioxidant that may effectively reduce the risk of developing CIN for patients with preexisting kidney disease. Despite the publication of more than 30 clinical trials and 10 metaanalyses, a therapeutic benefit of NAC has not been consistently demonstrated, and its therapeutic role remains controversial.[41,42] Nevertheless, its use should be considered, along with hydration, for all patients who are at high risk of toxicity.[35,40,42,44,50,52] The recommended *N*-acetylcysteine dosing regimen for prevention of CIN is to give four doses of 600 mg to 1,200 mg orally every 12 hours, with the first dose administered prior to contrast exposure (see Table 55–3).[34,42,50,52] Finally, other nephrotoxic drugs should be discontinued if possible, and subsequent contrast studies appropriately timed to minimize cumulative toxicity.

CLINICAL CONTROVERSY

Some clinicians believe that insufficient evidence exists to justify use of *N*-acetylcysteine for the prevention of contrast-induced nephrotoxicity, while others feel that its safety profile, ease of use, low cost, and potential for benefit are adequate justification for use for all patients.

Continuous venovenous hemofiltration (CVVH) may also be an effective means of preventing CIN.[53,54] However, because of the logistical issues (e.g., technical difficulty) and high cost of CVVH, currently this approach is not widely used and should be considered only for the highest risk patients in whom contrast exposure is unavoidable. Use of mannitol and furosemide for prevention may be harmful, and recent evidence indicates that fenoldopam, dopamine, and calcium channel blockers are ineffective in the prevention of CIN in CKD patients.[33,34] Consequently, these approaches are generally not recommended for the prevention of CIN.

Management Currently there is no specific therapy available for managing established CIN. Care is supportive as described in Chap. 51. Renal function (e.g., S_{cr}, urine output), electrolytes (e.g., sodium, potassium), and volume status should be closely monitored, and renal replacement therapy should be used as needed for patients when indicated (see Chap. 51).

Cisplatin Nephrotoxicity

Incidence Cisplatin is one of the most important and widely used antineoplastic drugs for the treatment of solid tumors, often demonstrating exceptional efficacy (i.e., cure rates over 90% in testicular cancers).[55,56] Unfortunately, the primary dose-limiting toxicity of platin-containing compounds is nephrotoxicity. The incidence of cisplatin nephrotoxicity was extremely high early in its development, with more than 70% of patients developing AKI in the 1980s.[55] Current estimates are much lower, primarily the result of limiting the total drug dose, reducing the rate of administration, and aggressively hydrating patients, yet it still occurs in 20% to 30% of patients and remains a significant cause of morbidity.[56,57] Carboplatin, a second-generation platinum analog, is associated with a lower incidence of nephrotoxicity than cisplatin and thus is the preferred agent in high-risk patients.[58]

Clinical Presentation Cisplatin administration results in impaired tubular reabsorption and decreased urinary concentration ability, leading to increased excretion of salt and water (i.e., polyuria) within 24 hours of treatment. Polyuria persists, and a decrease in GFR evidenced by a rise in S_{cr} concentration may be seen within 72 to 96 hours after cisplatin administration.[55,57] Serum creatinine peaks approximately 10 to 14 days after initiation of therapy, with recovery by 21 days. As many as 25% of patients may have reversible elevations in S_{cr} and BUN for 2 weeks after cisplatin treatment. However, kidney damage is dose related and cumulative with subsequent cycles of therapy, so the S_{cr} concentration may continue to rise, and irreversible kidney injury may result.[57] Hypomagnesemia is a hallmark finding of cisplatin nephrotoxicity, due to impaired magnesium reabsorption and thus increased urinary losses.[55] Hypomagnesemia is often accompanied by hypocalcemia and hypokalemia and may be severe, leading to seizures, neuromuscular irritability, or personality changes. Urinalysis typically reveals leukocytes, renal tubular epithelial cells, and granular casts.[57]

Pathogenesis The pathogenesis of cisplatin nephrotoxicity is multifactorial in nature and likely begins with cellular uptake and accumulation of the drug in proximal tubular epithelial cells to concentrations that may reach five times the serum concentration.[56,57] Tubular cell exposure to cisplatin then activates a series of cell signaling pathways, including the mitogen-activated protein kinase (MAPK) pathway, p53, caspase, and the generation of reactive oxygen species, that collectively promote tubular cell injury and death via necrosis and/or apoptosis. Simultaneous production of proinflammatory cytokines such as tumor necrosis factor-α (TNF-α) within tubular cells activates an inflammatory response which may worsen the renal insult.[56] Although tubular damage is evident in both the proximal and distal segments, the majority occurs in the proximal tubules and is followed by a progressive loss of glomerular filtration capacity and impaired distal tubular function. Renal biopsies generally reveal necrosis of proximal and distal tubules and collecting ducts, with no obvious morphological changes to the glomeruli.[57]

Risk Factors Risk factors include increased age, dehydration, renal irradiation, concurrent use of nephrotoxic drugs, large cumulative doses, and alcohol abuse.[55,57]

Prevention The best renoprotective strategy during cisplatin treatment incorporates a combination of interventions, including prospective dose reduction and decreased frequency of administration, which usually requires using the platin compounds in combination with other chemotherapeutic agents, avoiding concurrent use of other nephrotoxic drugs, and ensuring patients are euvolemic or somewhat hypervolemic prior to initiating treatment.[55,56] Vigorous hydration with isotonic saline should be used for all patients with a goal of maintaining at least 100 to 150 mL/h of urine output during and after cisplatin treatment. Hydration should be initiated 12 to 24 hours prior to and continued for 2 to 3 days after cisplatin administration at rates of 100 to 250 mL/h, as tolerated, to maintain a urine flow of 3 to 4 L/day.[55] Concurrent use of diuretics such as furosemide and mannitol to maintain urine flow has not been consistently demonstrated to be renoprotective; thus, their use is no longer recommended.[55]

Amifostine, an organic thiophosphate that is converted to an active metabolite, chelates cisplatin in normal cells and reduces the nephrotoxicity, neurotoxicity, ototoxicity, and myelosuppression associated with cisplatin and carboplatin therapy. It is also thought to serve as a thiol donor, thereby reducing intracellular reactive oxygen species and corresponding oxidative stress that plays a critical role in the development of cellular injury.[30,56] Pretreatment with amifostine should be considered for patients who are at high risk for kidney injury, particularly patients who are elderly, volume depleted, have CKD, or are receiving other nephrotoxic drugs concurrently. The current recommended dose of amifostine is 910 mg/m^2 administered intravenously over 15 minutes, beginning 30 minutes prior to cisplatin administration.[59] Common toxicities include acute hypotension, nausea, and fatigue.

Promising investigational techniques include the use of hypertonic saline (e.g., administration of each dose in 250 mL of 3% saline) to reduce tubular cisplatin uptake, *N*-acetylcysteine to reduce oxidative damage by acting as a sulfhydryl donor, and disulfiram metabolite diethyldithiocarbamate to reduce cytochrome P450 2E1-mediated generation of hydroxyl radicals.[55,56,60] Recently, the protective effect of melatonin and the ability of cisplatin-incorporated polymeric micelles to maintain antitumor activity while reducing nephrotoxicity were demonstrated. Finally, reduced renal exposure can be achieved with the use of localized intraperitoneal administration in conjunction with systemic administration of sodium thiosulfate for those with peritoneal tumors.[55]

Management AKI caused by cisplatin therapy is usually partially reversible with time and supportive care, including dialysis. Renal function indices should be closely followed, with S_{cr} and BUN concentrations checked daily. Serum magnesium, potassium, and calcium concentrations should be monitored daily and corrected as needed.[57] Hypocalcemia and hypokalemia may be difficult to

reverse until hypomagnesemia is corrected. Progressive kidney disease caused by cumulative nephrotoxicity may be irreversible and in some cases may lead to ESRD and require chronic dialysis support.

Amphotericin B Nephrotoxicity

Incidence Variable rates of amphotericin B nephrotoxicity have been reported that correspond in large part to the cumulative dose administered. Nephrotoxicity may be seen in nearly 30% of patients receiving median cumulative doses as low as 240 mg[61] and reaches an incidence of >80% when cumulative doses approach 5 g.[61,62] Although numerous studies demonstrate lower rates of nephrotoxicity with liposomal formulations compared with conventional amphotericin B, it is difficult to compare rates of toxicity between products and studies because of the variability in the study populations, doses administered, and inconsistent definitions of nephrotoxicity and methods of assessment.[63]

Clinical Presentation Dose-dependent nephrotoxicity is often evident after administration of cumulative doses of 2 to 3 g as nonoliguria, renal tubular potassium, sodium, and magnesium wasting, impaired urinary concentrating ability, and distal renal tubular acidosis.[1,11] Although the cumulative dose is a significant risk factor, the time to onset of kidney injury varies considerably, ranging from a few days to weeks.[61] Tubular dysfunction usually manifests 1 to 2 weeks after treatment is begun, and potassium and magnesium replacement may be necessary. This is typically followed by a decrease in GFR and a rise in S_{cr} and BUN concentrations.[64] Consequently, renal function indices should be closely followed, with S_{cr} and BUN concentrations checked daily, and serum magnesium, potassium, and calcium concentrations monitored every other day and corrected as needed.

Pathogenesis Amphotericin B nephrotoxicity occurs predominantly via two mechanisms. The first is direct tubular epithelial cell toxicity resulting from interaction of amphotericin B with ergosterol in the cell membrane, leading to increased tubular cell membrane permeability, lipid peroxidation, and eventual necrosis of proximal tubular cells.[61] Tubular injury appears to be exacerbated by ischemic injury, which is a result of a reduction in renal blood flow and GFR due to afferent arteriolar vasoconstriction.[11,61]

Risk Factors Risk factors that impact the likelihood of developing amphotericin B nephrotoxicity include preexisting kidney disease, large individual and cumulative doses, short infusion times, volume depletion, hypokalemia, increased age, and concomitant administration of diuretics and other nephrotoxins (cyclosporine in particular).[11,61,64]

Prevention Permanent decrements in GFR are best prevented by incorporating a low threshold [i.e., if S_{cr} reaches 2 mg/dL (177 μmol/L) on 2 consecutive days] for stopping amphotericin B or switching to a liposomal formulation.[65] Several liposomal amphotericin B formulations are now available and should be used in most high-risk patients as they have been reported to reduce nephrotoxicity by enhancing drug delivery to sites of infection and reducing interaction with tubular epithelial cell membranes.[61] Nephrotoxicity can also be minimized by limiting the cumulative dose, increasing the infusion time, ensuring the patient is well hydrated, and avoiding concomitant administration of other nephrotoxins.[11] Administration of 1 L intravenous 0.9% sodium chloride daily during the course of therapy appears to reduce toxicity and a single infusion of saline 10 to 15 mL/kg prior to administration of each dose of amphotericin B are generally recommended.[61] A number of other antifungal agents such as itraconazole, voriconazole, and caspofungin are viable alternatives and are now routinely used in lieu of amphotericin B for patients at high risk of developing nephrotoxicity.[11,65]

CLINICAL CONTROVERSY

Although liposomal formulations of amphotericin B are dramatically more expensive than conventional amphotericin B (i.e., $300 to $1,000 per day vs $5 per day),[66] many clinicians recommend using liposomal formulations for all patients with CKD and those at risk for developing nephrotoxicity. Others maintain that the safety and efficacy of liposomal formulations are not yet established enough to warrant their use for all patients.

Management Amphotericin B nephrotoxicity is best treated by discontinuation of therapy and substitution of alternative antifungal therapy, if possible. Renal tubular dysfunction and glomerular filtration will improve gradually to some degree in most patients, but damage may be irreversible. Renal function indices should be closely followed, with S_{cr} and BUN concentrations checked daily, and serum magnesium, potassium, and calcium concentrations should be monitored daily and corrected as needed.[11]

OSMOTIC NEPHROSIS

The term *sucrose nephrosis* was first used in 1940 to describe renal lesions observed at autopsy in patients who died of severe AKI following parenteral administration of hyperosmolar sucrose.[67] The lesions were characterized by severe swelling and vacuolization of the proximal tubular epithelial cells. Subsequently, the term *osmotic nephrosis* was used to describe the lesion in light of the suspected mechanism, an osmotic gradient between the tubular lumen and epithelial cells.[67] It is now known that several drugs, including mannitol, low-molecular-weight dextran, hydroxyethyl starch, and radiographic contrast media, or drug vehicles, such as sucrose, maltose, and propylene glycol, are associated with osmotic nephrosis, which may rarely lead to ATN and AKI.[24,67–69] Since osmotic nephrosis does not necessarily negatively affect proximal tubular function, its presence may often go undetected in patients without overt signs of ATN. This likely contributes to the extremely low incidence of osmotic nephrosis reported for causative agents.[67] Intravenous immunoglobulin solutions containing hyperosmolar sucrose may cause osmotic nephrosis and AKI in 1% to 10% of cases, which is usually reversible shortly after discontinuing therapy.[67,70] Recently, maltose-based intravenous immunoglobulin solutions have also been implicated in the development of osmotic nephrosis.[68,71] Although intravenous immunoglobulin-induced nephropathy is the modern prototype for osmotic nephrosis, it is understood that the vehicle (i.e., sucrose or maltose) is the culprit and not the immunoglobulins themselves.

The clinical presentation of osmotic nephrosis is often subtle. While tubular proteinura or vacuolated tubular cells may be observed on urinalysis for patients with AKI, the definitive diagnosis of osmotic nephrosis is only made via a kidney biopsy.[67] Intravenous immunoglobulin-induced AKI typically presents as oliguria after 3 to 4 days of treatment and may persist for up to 2 weeks.[24] Kidney injury occurs via uptake of the offending agent through pinocytosis into proximal tubular epithelial cells, subsequent formation of vacuoles, and accumulation of lysosomes, which collectively results in an oncotic gradient and thus cellular swelling, tubular luminal occlusion, and compromised cellular integrity.[24,67] Renal replacement therapy may be necessary for up to 40% of patients developing osmotic nephrosis-associated AKI.[67] However, it is usually reversible, with 80% of patients recovering normal renal function following withdrawal of the offending drug.[24]

Risk factors for osmotic nephrosis include excessive doses of offending agents, preexisting kidney disease, ischemia, older age (>65 years), and concomitant use of other nephrotoxins, particularly cyclosporine.[24,67] Nephrotoxicity may be prevented by limiting the dose, reducing the rate of infusion, and avoiding dehydration and concomitant nephrotoxins.

HEMODYNAMICALLY MEDIATED KIDNEY INJURY

4 Hemodynamically mediated kidney injury generally refers to any cause of AKI resulting from an acute decrease in intraglomerular pressure, including "prerenal" states leading to reduced effective renal blood flow (e.g., hypovolemia, congestive heart failure) and medications that affect the renin–angiotensin system.[11,12,23] The kidneys receive approximately 25% of resting cardiac output, which renders them particularly susceptible to alterations in renal blood flow and enhances their exposure to circulating drugs.[17] Within each nephron, blood flow and pressure are regulated by glomerular afferent and efferent arterioles to maintain intraglomerular capillary hydrostatic pressure, glomerular filtration, and urine output. Afferent and efferent arteriolar vasoconstrictions are primarily mediated by angiotensin II, whereas afferent vasodilation is primarily mediated by prostaglandins (Fig. 55–1).[72] This specialized blood flow is precisely regulated by interrelations between arachidonic acid metabolites, natriuretic factors, nitric oxide, the sympathetic nervous system, the renin–angiotensin system, and the macula densa response to distal tubular solute delivery.[72,73] Drug-induced causes of hemodynamic kidney injury typically stem from constriction of glomerular afferent arterioles and/or dilation of glomerular efferent arterioles. ACEIs, angiotensin II receptor blockers, and NSAIDs are the agents that have been most commonly implicated.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS AND ANGIOTENSIN II RECEPTOR BLOCKERS

Incidence

The incidence of ACEI- or angiotensin II receptor blocker (ARB)-mediated kidney injury has not been established. Patients with renal artery stenosis, volume depletion, and congestive heart failure and those with preexisting kidney disease, including diabetic nephropathy, are most likely to experience a significant decline in renal function when therapy with one of these agents is initiated.[74] For example, between 20% to 25% of hospitalized patients with congestive heart failure develop AKI after treatment with ACEIs is intiated.[75,76] The incidence of ACEI induced AKI may be as high as 23% for patients with bilateral renal artery stenosis and up to 38% for patients with unilateral renal artery stenosis.[10]

Clinical Presentation

Therapy with ACEIs and ARBs will acutely reduce GFR; so a moderate rise in S_{cr} after initiation of therapy should be anticipated.[74] Importantly, a distinction must be made between a potentially detrimental reduction in GFR and a normal, predictable rise in S_{cr}. An increase in S_{cr} of up to 30% is commonly observed within 3 to 5 days of initiating therapy and is an indication that the drug has begun to exert its desired pharmacologic effect.[11,74] The increase in S_{cr} typically stabilizes within 1 to 2 weeks and is usually reversible upon stopping the drug. Furthermore, an association exists between acute increases in S_{cr} of ≤30% from baseline that stabilize within the first 2 months of initiating therapy and preservation of renal function. The S_{cr} threshold for discontinuation of ACEI or ARB therapy is unclear.[74] However, an increase in S_{cr} of more than 30% above baseline in the course of 1 to 2 weeks may necessitate discontinuation of the offending drug.

Pathogenesis

The pathogenesis of ACEI- or ARB-mediated kidney injury is the result of disruption of normal autoregulation of intraglomerular capillary hydrostatic pressure.[11] Normally, the kidney attempts to maintain GFR by dilating the afferent arteriole and constricting the efferent arteriole in response to a decrease in renal blood flow. During states of reduced blood flow, the juxtaglomerular apparatus increases renin secretion. Plasma renin converts angiotensinogen to angiotensin I, and ultimately angiotensin II by angiotensin-converting enzyme. Angiotensin II constricts the afferent and efferent arterioles, but has a greater effect on the efferent arterioles, resulting in a net increase in intraglomerular pressure.[74] Additionally, renal prostaglandins, prostaglandin E_2 in particular, are released and induce a net dilation of the afferent arteriole, thereby improving blood flow into the glomerulus. Together these processes maintain GFR and urine output (Fig. 55–2).[23,72,73]

ACEI- or ARB-mediated kidney injury is the result of a decrease in glomerular capillary hydrostatic pressure sufficient to reduce

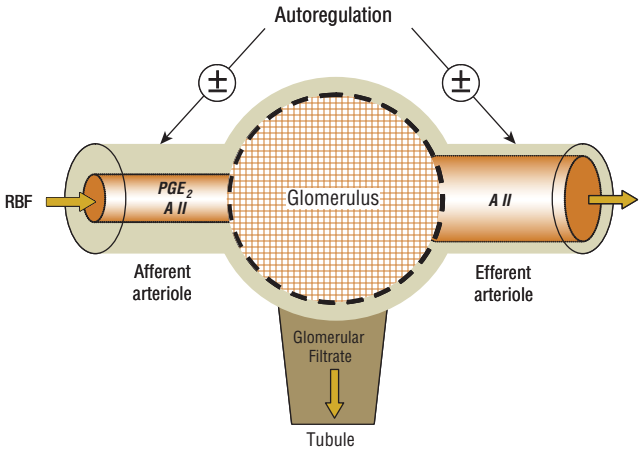

FIGURE 55-1. Normal glomerular autoregulation serves to maintain intraglomerular capillary hydrostatic pressure, glomerular filtration rate (GFR), and, ultimately, urine output. (A II, angiotensin II; PGE_2, prostaglandin E_2; RBF, renal blood flow.)

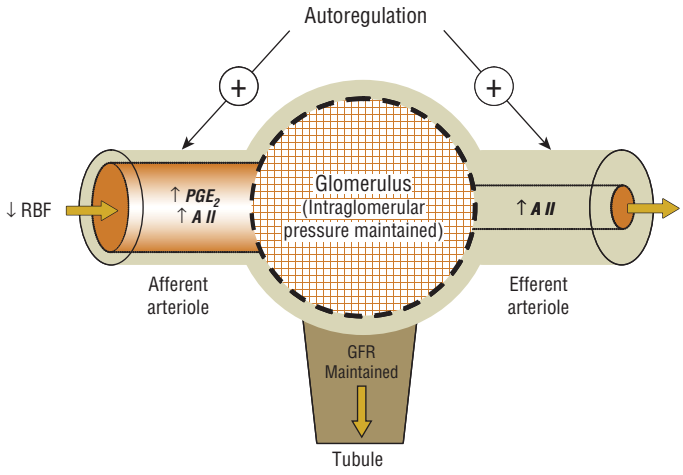

FIGURE 55-2. Glomerular autoregulation during "prerenal" states (i.e., reduced blood flow). (A II, angiotensin II; GFR, glomerular filtration rate; PGE_2, prostaglandin E_2; RBF, renal blood flow.)

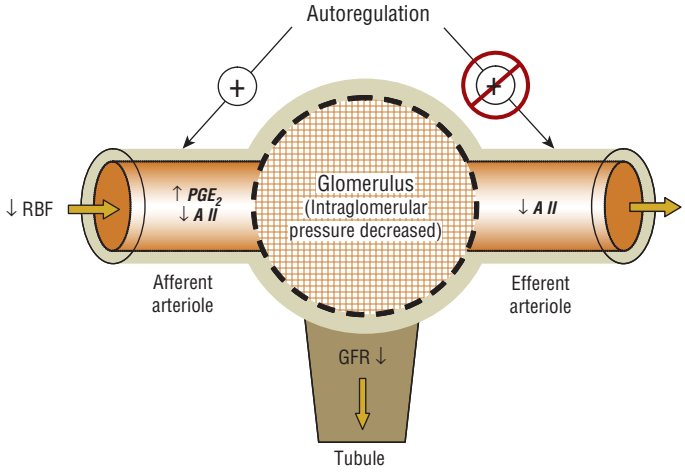

FIGURE 55-3. Pathogenesis of angiotensin-converting enzyme inhibitor (ACEI) nephropathy. (A II, angiotensin II; GFR, glomerular filtration rate; PGE_2, prostaglandin E_2; RBF, renal blood flow.)

glomerular ultrafiltration.[24] When ACEI therapy (e.g., enalapril or ramipril) is initiated, the synthesis of angiotensin II is decreased, thereby preferentially dilating the efferent arteriole. This reduces outflow resistance from the glomerulus and decreases hydrostatic pressure in the glomerular capillaries, which alters Starling forces across the glomerular capillaries to decrease intraglomerular pressure and GFR and then often leads to nephrotoxicity, particularly in the setting of reduced renal blood flow or effective arterial blood volume (Fig. 55–3), that is, prerenal settings in which glomerular afferent arteriolar blood flow is reduced and the efferent arteriole is vasoconstricted to maintain sufficient glomerular capillary hydrostatic pressure for ultrafiltration.[12,24]

Risk Factors

Patients at greatest risk are those dependent on angiotensin II and renal efferent arteriolar constriction to maintain blood pressure and GFR.[24,74] These include patients with bilateral renal artery stenosis or stenosis in a single kidney (i.e., renal transplant); patients with decreased effective arterial blood volume (i.e., prerenal states), especially those with congestive heart failure, volume depletion from excess diuresis or gastrointestinal fluid loss, hepatic cirrhosis with ascites, and nephrotic syndrome; patients with preexisting kidney disease; and patients receiving concurrent nephrotoxic drugs, particularly other drugs that affect intraglomerular autoregulation.[12,74]

Prevention

Hemodynamically mediated AKI caused by ACEIs or ARBs is frequently preventable by recognizing the presence of preexisting kidney disease or decreased effective renal blood flow as a result of volume depletion, heart failure, or liver disease. A common strategy for at-risk patients is to initiate therapy with very low doses of a short-acting ACEI (e.g., captopril 6.25 mg to 12.5 mg), then gradually titrate the dose upward and convert to a longer-acting agent after patient tolerance has been demonstrated. Outpatients may be started on low doses of long-acting ACEIs (e.g., enalapril 2.5 mg) with gradual dose titration every 2 to 4 weeks until the maximum dose or desired response is achieved. Renal function indices and serum potassium concentrations must be monitored carefully, daily for hospitalized patients and every 2 to 3 days for outpatients. Monitoring may need to be more frequent during outpatient initiation of ACEI or ARB therapy for patients with preexisting kidney disease, congestive heart failure, or suspected renovascular disease. Use of concurrent hypotensive agents and other drugs that affect renal hemodynamics (e.g., NSAIDs, diuretics) should be discouraged and dehydration avoided.

Management

Acute decreases in renal function and the development of hyperkalemia usually resolve over several days after ACEI or ARB therapy is discontinued. Occasionally patients will require management of severe hyperkalemia, as described in detail in chapter 60.

ACEI or ARB therapy may frequently be reinitiated, particularly for patients with congestive heart failure, after intravascular volume depletion has been corrected or diuretic doses reduced. Slight reductions in renal function [maintenance of a S_{cr} concentration of 2 to 3 mg/dL (177 to 265 μmol/L)] may be an acceptable tradeoff for hemodynamic improvement in certain patients with severe congestive heart failure or renovascular disease not amenable to revascularization.[77]

NONSTEROIDAL ANTIINFLAMMATORY DRUGS AND SELECTIVE CYCLOOXYGENASE-2 INHIBITORS

Incidence

The overall safety of NSAIDs is evidenced by the nonprescription availability in the United States of several drugs in the class (e.g., ibuprofen, naproxen, ketoprofen). Although potential adverse renal effects from nonprescription NSAIDs had been a concern, conventional nonselective NSAIDs and selective cyclooxygenase-2 (COX-2) inhibitors are unlikely to acutely affect kidney function in the absence of renal ischemia or excess renal vasoconstrictor activity.[11,78,79] Nevertheless, given their general safety and widespread availability, NSAIDs are among the most commonly used drugs. More than 30 million people take NSAIDs daily worldwide.[78] Although the incidence of NSAID-induced AKI is unclear, historical reports suggest that 500,000 to 2.5 million people develop some degree of NSAID nephrotoxicity in the United States annually.[80]

Clinical Presentation

NSAID- and COX-2-induced AKI can occur within days of initiating therapy, particularly with a short-acting agent such as ibuprofen, or within days of some other precipitating event (e.g., intravascular volume depletion). Patients typically present with complaints of diminished urine output, weight gain, and/or edema. Urine sodium concentrations [<20 mEq/L (<20 mmol/L)] and fractional excretion of sodium [<1% (0.01)] are usually low, and BUN, S_{cr}, potassium, and blood pressure are typically elevated.[22,81] The urine sediment is usually bland and unchanged from baseline but may show occasional granular casts.

Pathogenesis

The pathogenesis of NSAID- and COX-2-induced AKI lies in the disruption of normal intraglomerular autoregulation.[11,79,81] Specifically, NSAIDs inhibit cyclooxygenase (COX)-catalyzed synthesis of vasodilatory prostaglandins, including prostaglandins I_2 (prostacyclin) and E_2, from arachidonic acid.[79] These prostaglandins are synthesized in the renal cortex and medulla by vascular endothelial and glomerular mesangial cells, and their effects are primarily local and result in net afferent arteriolar vasodilation.[79,81] Vasodilatory prostaglandins have limited activity in states of normal renal blood flow, but in states of decreased renal blood flow their synthesis is increased and they serve a vital autoregulatory role in the protection against renal ischemia and hypoxia by antagonizing renal arteriolar vasoconstriction due to angiotensin

II, norepinephrine, endothelin, and vasopressin.[24,79] Thus, administration of NSAIDs in the setting of reduced renal blood flow will blunt the usual compensatory increase in prostaglandin activity, altering the normal autoregulatory balance in favor of renal vasoconstrictors, thereby promoting renal ischemia and a reduction in glomerular filtration.[81]

Risk Factors

Risk factors for NSAID- and COX-2-induced AKI include age >60 years, preexisting kidney disease, hepatic disease with ascites, congestive heart failure, intravascular volume depletion/dehydration, concurrent diuretic therapy, or systemic lupus erythematosus.[11,24,81] The elderly are at higher risk because of multiple comorbidities, multiple-drug therapies, and reduced renal hemodynamics. Combined use of NSAIDs or COX-2 inhibitors and concurrent nephrotoxic drugs, particularly other drugs that affect intraglomerular autoregulation should be avoided in high-risk patients.[11]

Prevention

NSAID- and COX-2 inhibitor-induced AKI can be prevented by recognizing high-risk patients, avoiding potent compounds such as indomethacin and using analgesics with less prostaglandin inhibition, such as acetaminophen, nonacetylated salicylates, aspirin, and possibly nabumetone.[11,81] Nonnarcotic analgesics (e.g., tramadol) may also be useful but do not provide antiinflammatory activity. When NSAID therapy is essential for high-risk patients, the minimal effective dose should be used for the shortest duration possible, and NSAIDs with short half-lives should be considered (e.g., sulindac) along with optimal management of predisposing medical problems and frequent renal function monitoring.[11] Moreover, use of concurrent hypotensive agents and other drugs that affect renal hemodynamics (e.g., ACEIs, ARBs, diuretics) should be discouraged in high-risk patients and dehydration avoided.

Traditional, nonselective NSAIDs inhibit COX-1 and COX-2, whereas the selective drugs meloxicam, celecoxib, and valdecoxib preferentially inhibit COX-2. COX-2 inhibitors were anticipated to be beneficial in high-risk patients. However, recent data indicate that they affect renal function similarly to nonselective NSAIDs, and thus caution is warranted with their use, particularly in high-risk patients.[11,81]

Management

NSAID-induced AKI is treated by discontinuation of therapy and supportive care. Kidney injury is rarely severe, and recovery is usually rapid. Occasionally, the hemodynamic insult is sufficiently severe to cause ATN, which can prolong injury.[24]

CYCLOSPORINE AND TACROLIMUS

The calcineurin inhibitors cyclosporine and tacrolimus have dramatically enhanced the success of solid-organ transplantation. As many as 94% of kidney transplant patients are prescribed a calcineurin inhibitor-based immunosuppressive regimen.[82] Nephrotoxicity, however, remains a major dose-limiting adverse effect of both drugs. Although delayed chronic interstitial nephritis has also been reported, acute hemodynamically mediated kidney injury is an important mechanism of calcineurin inhibitor-induced nephrotoxicity.

Incidence

Historically, reversible AKI occurred frequently in transplant recipients during the first 6 months of cyclosporine therapy. The 5-year risk of CKD after transplantation of a nonrenal organ ranges from 7% to 21%, depending on the type of organ transplanted, and the occurrence of CKD in these patients is associated with more than a fourfold increase in the risk of death.[83]

Clinical Presentation

The clinical presentation of acute nephrotoxicity associated with calcineurin inhibitors (i.e., hemodynamically mediated AKI) is quite different from the presentation of chronic nephrotoxicity (see Chronic Interstitial Nephritis below). AKI may occur within days of initiating therapy, manifesting as a rise in S_{cr} concentration and a corresponding decline in creatinine clearance.[11,84] Hypertension, hyperkalemia, sodium retention, oliguria, renal tubular acidosis, and hypomagnesemia are frequently observed in the absence of urine sediment abnormalities or morphologic lesions.[11,82] On the other hand, renal biopsy may reveal thickening of arterioles, mild focal glomerular sclerosis, proximal tubular epithelial cell vacuolization and atrophy, and interstitial fibrosis. Biopsy is most useful to distinguish acute calcineurin inhibitor nephrotoxicity from acute cellular rejection of the transplanted kidney, the latter being evidenced by interstitial infiltrates composed of activated lymphocytes (see Chap. 98).[84]

Pathogenesis

The acute hemodynamic changes associated with calcineurin inhibitor nephrotoxicity result from an increase in potent vasoconstrictors including thromboxane A_2 and endothelin, activation of the renin–angiotensin and sympathetic nervous systems, as well as a reduction in the vasodilators nitric oxide, prostacyclin, and prostaglandin E_2.[82,84] The net effect is an imbalance in afferent and efferent tone, resulting in predominantly afferent vasoconstriction with reduced renal plasma flow and GFR.[11] The mechanism of acute nephrotoxicity is generally thought to be dose related, since renal function improves rapidly following dose reduction.[11]

Risk Factors

Risk factors include age over 65, higher dose, concomitant therapy with nephrotoxic drugs (particularly NSAIDs), and interacting drugs that inhibit calcineurin inhibitor metabolism and transport and thus increase systemic exposure, older kidney allograft age, salt depletion, diuretic use, and polymorphic expression of P-glycoprotein.[82] The incidence of AKI with potential progression to chronic nephropathy has decreased since the introduction of lower-dose-therapy regimens. Unfortunately, there has been no apparent reduction in the incidence of the slow, dose-dependent decline in glomerular filtration.[84]

Prevention

Because acute hemodynamically mediated kidney injury secondary to cyclosporine and tacrolimus appears to be concentration related, pharmacokinetic and pharmacodynamic monitoring is an important means of preventing toxicity.[82] However, the persistent presence of therapeutic or low cyclosporine concentrations does not totally preclude the development of nephrotoxicity. Calcium channel blockers may antagonize the vasoconstrictor effect of cyclosporine by dilating glomerular afferent arterioles and preventing acute decreases in renal blood flow and glomerular filtration.[82] Lastly, decreased doses of cyclosporine or tacrolimus, primarily when used in combination with other nonnephrotoxic immunosuppressants, may minimize the risk of toxicity, but this may increase the risk of chronic rejection.[84]

Management

AKI usually improves with dose reduction and treatment of contributing illness or the discontinuation of interacting drugs.

CKD is usually irreversible, but progressive toxicity may be limited by discontinuation of cyclosporine (or tacrolimus) therapy or dose reduction, with the continuation of other immunosuppressants.[82,84] S_{cr} and BUN should be closely monitored (daily if possible), as should cyclosporine or tacrolimus concentrations, to ensure that serum concentrations are within the narrow therapeutic range.

CRYSTAL NEPHROPATHY

Crystal nephropathy is caused by precipitation of drug crystals in distal tubular lumens, which commonly leads to intratubular obstruction, interstitial nephritis, and occasionally superimposed ATN. Nephrolithiasis is a type of crystal nephropathy that results from abnormal crystal precipitation in the renal collecting system, potentially causing urinary tract obstruction with kidney injury. Numerous medications have been associated with development of crystal nephropathy (Table 55–4).

INTRATUBULAR OBSTRUCTION

Drugs may induce crystal nephropathy with subsequent intratubular obstruction and AKI by direct (precipitation of the drug itself) and indirect means (i.e., promoting release and precipitation of tissue-degradation products). Antineoplastic drugs may cause acute renal tubular obstruction indirectly by inducing tumor lysis syndrome, hyperuricemia, and intratubular precipitation of uric acid crystals.[85] Acute oliguric or anuric kidney injury develops rapidly.

TABLE 55-4 Drugs Associated with Allergic Interstitial Nephritis

Antimicrobials	
Acyclovir	Indinavir
Aminoglycosides	Rifampin
Amphotericin B	Sulfonamides
β-Lactams	Tetracyclines
Erythromycin	Trimethoprim-sulfamethoxazole
Ethambutol	Vancomycin
Diuretics	
Acetazolamide	Loop diuretics
Amiloride	Triamterene
Chlorthalidone	Thiazide diuretics
Neuropsychiatric	
Carbamazepine	Phenytoin
Lithium	Valproic acid
Phenobarbital	
Nonsteroidal antiinflammatory drugs	
Aspirin	Ketoprofen
Indomethacin	Phenylbutazone
Naproxen	Diclofenac
Ibuprofen	Zomepirac
Diflunisal	Cyclooxygenase-2 inhibitors
Piroxicam	
Miscellaneous	
Acetaminophen	Lansoprazole
Allopurinol	Methyldopa
Interferon-alfa	Omeprazole
Aspirin	*P*-aminosalicylic acid
Azathioprine	Phenylpropanolamine
Captopril	Propylthiouracil
Cimetidine	Radiographic contrast media
Clofibrate	Ranitidine
Cyclosporine	Sulfinpyrazone
Glyburide	Warfarin sodium
Gold	

The diagnosis is supported by a urine uric acid-to-creatinine ratio greater than 1. Uric acid precipitation can be prevented by vigorous pretreatment hydration with normal saline, beginning at least 48 hours prior to chemotherapy, to maintain urine output 100 mL/h in adults, administration of allopurinol 100 mg/m^2 thrice daily (maximum of 800 mg/day) started 2 to 3 days prior to chemotherapy, and urinary alkalinization to pH 7.0.[86]

Drug-induced rhabdomyolysis is another form of indirect toxicity, which can lead to intratubular precipitation of myoglobin and, if severe, AKI.[87] The most common cause of drug-induced rhabdomyolysis is direct myotoxicity from 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors or statins, including lovastatin and simvastatin. The risk of rhabdomyolysis is increased when these drugs are administered concurrently with gemfibrozil, niacin, or inhibitors of the CYP3A4 metabolic pathway (e.g., erythromycin and itraconazole).[88]

Intratubular precipitation of drugs or their metabolites can also directly cause AKI. Precipitation of drug crystals is due primarily to supersaturation of a low urine volume with the offending drug or relative insolubility of the drug in either alkaline or acidic urine.[89] Volume depletion is an important risk factor for the development of AKI. Urine pH decreases to approximately 4.5 during maximal stimulation of renal tubular hydrogen ion secretion. Certain solutes can precipitate and obstruct the tubular lumen at this acid pH, particularly when urine is concentrated, such as for patients with volume depletion. For example, several antiviral drugs have been associated with intratubular precipitation and AKI.[19,89,90] Acyclovir is relatively insoluble at physiologic urine pH and is associated with intratubular precipitation in dehydrated oliguric patients.[19,89] Foscarnet complexation with ionized calcium may result in precipitation of calcium-foscarnet salt crystals in renal glomeruli, causing primarily a crystalline glomerulonephritis. The salt crystals may then secondarily precipitate in the renal tubules causing tubular necrosis. The protease inhibitor indinavir has been associated with crystalluria, crystal nephropathy, dysuria, urinary frequency, back and flank pain, or nephrolithiasis in approximately 8% of treated patients.[89,90] Intratubular indinavir crystal precipitation can be prevented in nearly 75% of treated patients if one assures that the patient consumes at least 2 to 3 L of fluid per day.[89] Sulfadiazine, when used at high doses, and methotrexate may also precipitate in acidic urine and can cause oligoanuric kidney injury.[89] Massive administration of ascorbic acid can also result in obstruction of renal tubules with calcium oxalate crystals. Oxalate, a poorly soluble ascorbic acid metabolite, can also precipitate and worsen renal function when ascorbic acid is administered to patients with AKI, congenital nephrotic syndrome, and renal transplant patients.[89,91,92] Triamterene and the quinolone antibiotic ciprofloxacin may also precipitate in renal tubules and cause kidney injury.[89]

Kidney injury caused by intratubular precipitation of most tissue-degradation products or drugs and their metabolites can be largely prevented and possibly treated by administering the drug after vigorously prehydrating the patient, maintaining a high urine volume, and urinary alkalinization.[89]

NEPHROCALCINOSIS

Nephrocalcinosis is a clinical–pathologic condition characterized by extensive tubulointerstitial precipitation and deposition of calcium phosphate crystals leading to marked tubular calcification.[93–95] It is most commonly seen in clinical conditions associated with hypercalcemia and hypercalciuria, such as hyperparathyroidism, malignancy, and less frequently increased intake of calcium or vitamin D. However, nephrocalcinosis can also result from hyperphosphatemia and hyperphosphaturia in the absence of hypercalcemia,

as is known to occur for patients who have received oral sodium phosphate solution (OSPS) as a bowel preparation.[94,96]

Acute Phosphate Nephropathy

The term *acute phosphate nephropathy* was coined specifically to describe OSPS-induced nephrocalcinosis, as its pathogenesis is the result of increased phosphate intake rather than hypercalcemia.[95] During the last decade, several cases of nephrocalcinosis have been reported after use of OSPS for bowel preparation prior to gastrointestinal procedures,[93,95,97–99] and strong associations have recently been demonstrated between exposure to OSPS and a decline in kidney function, particularly in the elderly and those with preexisting kidney disease.[100–102] The incidence of acute phosphate nephropathy is between 1 in 1,000 and 1 in 5,000 exposures, translating to roughly 1,400 to 7,000 new cases annually.[96] Patients usually present with AKI several days to months after exposure to OSPS. Patients in one cohort of 21 cases of acute phosphate nephropathy presented with AKI and a mean S_{cr} of 3.9 mg/dL (345 μmol/L) at a median of 1 month after colonoscopy.[95] Low-grade proteinuria (<1.0 g/day), normocalcemia, and bland urinary sediment are usually observed. Extensive deposition of calcium phosphate in the distal tubules and collecting ducts without glomerular or vascular injury is the hallmark of acute phosphate nephropathy.[93,95] Risk factors include advanced age, preexisting kidney disease, female sex, hypertension, diabetes, bowel conditions associated with prolonged intestinal transit, high sodium phosphate dosage, volume depletion, and medications that affect renal perfusion or function (e.g., diuretics, lithium, NSAIDs, ACEIs, or ARBs).[94]

NEPHROLITHIASIS

Nephrolithiasis (formation of renal calculi or kidney stones) does not present as classic nephrotoxicity since GFR is usually not decreased. Drug-induced nephrolithiasis can be the result of abnormal crystal precipitation in the renal collecting system, potentially causing pain, hematuria, infection, or, occasionally, urinary tract obstruction with kidney injury. The overall prevalence of drug-induced nephrolithiasis is estimated to be 1%.[103]

Kidney stone formation, possibly also accompanied by intratubular precipitation of crystalline material, has been a rare complication of drug therapy. Until the acquired immune deficiency syndrome (AIDS) era, triamterene had been the drug most frequently associated with kidney stone formation, with a prevalence of 0.4%.[103] Sulfadiazine is a poorly soluble sulfonamide that has caused symptomatic acetylsulfadiazine crystalluria with stone formation and flank or back pain, hematuria, or kidney injury in up to 29% of patients treated with the drug.[89] A high urine volume and urinary alkalinization to pH >7.15 may be protective. Numerous other drugs have been implicated in the development of nephrolithiasis, including the antiviral drugs nelfinavir and foscarnet, the antibacterial agents ciprofloxacin, amoxicillin, and nitrofurantoin, and various products containing ephedrine, norephedrine, and pseudoephedrine.[103] Most recently, a catastrophic outbreak of nephrolithiasis occurred in China stemming from consumption of melamine-contaminated dairy products. Most of those affected were children younger than 3 years of age. The now classic presentation consisted of dysuria, hematuria, occasional proteinuria, and stone passage: AKI occurred in 2.5% of the cases.[104]

GLOMERULAR DISEASE

Proteinuria, particularly nephrotic range proteinuria (defined as urine protein excretion greater than 3.5 g/day per 1.73 m^2) with or without a decline in the GFR is a hallmark sign of glomerular injury (see Chap. 56).[105] Several different glomerular lesions may occur, including minimal change disease, focal segmental glomerulosclerosis, and membranous nephropathy, mostly by immune mechanisms rather than direct cellular toxicity. Although drug-induced glomerular disease is uncommon, a variety of agents have been implicated.[106]

Minimal Change Glomerular Disease

Drug-induced minimal change glomerular disease is frequently accompanied by interstitial nephritis and is most common during NSAID therapy.[105] Lithium, quinolone antibiotics, and interferon-α have also been implicated.[24,25,106] Patients present abruptly with nephrotic range proteinuria, hypoalbuminemia, and hyperlipidemia and rarely with hematuria and hypertension.[25,105] The pathogenesis is unknown, but nephrotic range proteinuria as a consequence of NSAID therapy is frequently associated with a T-lymphocytic interstitial infiltrate, suggesting disordered cell-mediated immunity. Proteinuria usually resolves rapidly after discontinuation of the offending drug, and a 3- to 4-week course of corticosteroids may help resolve the lesion. More than 90% of adults achieve complete remission over the course of several months.[105]

Focal Segmental Glomerulosclerosis

Focal segmental glomerulosclerosis (FSGS) is characterized by patchy areas (i.e., only some glomeruli are partially affected by the disease) of glomerular sclerosis with interstitial inflammation and fibrosis (see Chap. 56). FSGS is becoming the most common cause of nephrotic syndrome in African Americans and whites in the United States.[105] It represents a pattern of glomerular injury, not a disease per se, and is the final common pathway by which normal glomerular components are replaced by fibrous scar tissue. FSGS has been described in the setting of chronic heroin abuse (known as *heroin nephropathy*).[107] The pathogenesis is unknown but may include direct toxicity by heroin or adulterants and injury from bacterial or viral infections accompanying intravenous drug use. The bisphosphonates pamidronate and zoledronate, commonly used to treat osteoporosis, malignancy-associated hypercalcemia, and Paget disease, are associated with the development of a particularly aggressive variant of FSGS called *collapsing glomerulopathy*.[108] It presents with massive proteinuria (>8 g/day), and it is typically characterized by rising S_{cr} at diagnosis and rapid progression to ESRD.[105,109] Patients receiving intravenous formulations, high doses, or prolonged therapy are at highest risk.[108]

Membranous Nephropathy

Membranous nephropathy is characterized by subepithelial immune complex formation along glomerular capillary loops and, although rarely seen, has classically been associated with gold therapy, penicillamine, captopril, and NSAID use.[25,106] Patients present with nephrotic range proteinuria and microscopic hematuria, with hypertension and elevated S_{cr} apparent for patients with more advanced disease.[105] The pathogenesis may involve damage to proximal tubule epithelium with antigen release, antibody formation, and glomerular immune complex deposition. Proteinuria usually resolves slowly after discontinuing the offending drug. Patients who remain nephrotic after 6 months should be treated with a 6 to 12 month course of immunosuppressive therapy, which typically consists of prednisone and cyclophosphamide.[105]

TUBULOINTERSTITIAL NEPHRITIS

Tubulointerstitial nephritis refers to diseases in which the predominant changes occur in the renal interstitium rather than the tubules. The presentation may be acute and reversible with interstitial

edema, rapid loss of renal function, and systemic symptoms or chronic and irreversible, associated with interstitial fibrosis and minimal to no systemic symptoms.[21,25]

ACUTE ALLERGIC INTERSTITIAL NEPHRITIS

Incidence

5 The incidence of drug-induced acute allergic interstitial nephritis (AIN) is unclear and likely varies with clinical setting. For example, the incidence has been estimated to be 0.7 cases per 100,000 young outpatient men but from 10% to 27% of kidney biopsies performed in hospitalized patients with unexplained AKI demonstrate AIN.[110–112] Multiple drugs have been implicated in the development of AIN (Table 55–4).[21,24,25] It usually manifests 2 weeks after exposure to a drug but may occur sooner if the patient was previously sensitized.[113]

Clinical Presentation Although methicillin-induced AIN is the prototype for AIN, it is now recognized that AIN is associated with all β-lactam antibiotics (including cephalosporins) and numerous other antimicrobials. Clinical signs present approximately 14 days after initiation of therapy and include (with their approximate incidence) fever (27% to 80%), maculopapular rash (15% to 25%), eosinophilia (23% to 80%), arthralgia (45%), and oliguria (50%).[110,112,113] Systemic hypersensitivity findings of the classic triad of fever, rash, and arthralgia, often along with eosinophilia and eosinophiluria, strongly suggest the diagnosis of AIN. However, this constellation of findings is not consistently reliable as one or more are frequently absent; so caution is warranted in basing diagnosis on hypersensitivity findings alone.[110,112] Eosinophiluria, an important marker of drug-induced AIN, is frequently absent, possibly because of fragility of eosinophils in urine and inadequate laboratory methodology. Anemia, leukocytosis, and elevated immunoglobulin E levels may occur. Tubular dysfunction may be manifested by acidosis, hyperkalemia, salt wasting, and concentrating defects.[21,113] The clinical presentation of AIN caused by proton pump inhibitors, which has recently been observed, is similar to that of β-lactams.[114–116]

NSAID-induced AIN has a different clinical presentation than that seen with most other drugs.[24] Patients are typically over 50 years of age (reflecting NSAID use for degenerative joint disease), the onset is delayed a mean of 6 months from initiation of therapy compared with 2 weeks with β-lactams, and there is a much lower incidence of fever, rash, and eosinophilia, which collectively may be observed in <10% of patients.[24,110,112] Concomitant nephrotic syndrome (proteinuria >3.5 g/day) occurs in more than 70% of patients. Prompt diagnosis of AIN is important as discontinuation of the offending drug may prevent irreversible renal damage.[21] Renal biopsy is the most definitive method for diagnosis.

Pathogenesis The pathogenesis of the majority of cases of AIN is considered to be an allergic hypersensitivity response. This is supported by the fact that AIN is characterized as a diffuse or focal interstitial infiltrate of lymphocytes, eosinophils, and occasional polymorphonuclear neutrophils.[21,113] Granulomas and tubular epithelial cell necrosis are relatively common with drug-induced AIN. Occasionally a humoral antibody-mediated mechanism is implicated by the presence of circulating antibody to a drug hapten–tubular basement membrane complex, low serum complement levels, and deposition of immunoglobulin G and complement in the tubular basement membrane.[21] More commonly, a cell-mediated immune mechanism is suggested by the absence of these findings and the presence of a predominantly T-lymphocyte.[113]

Risk Factors No specific risk factors have been identified because these are idiosyncratic hypersensitivity reactions. Individuals with other drug allergies may have increased risk and warrant close monitoring.

Prevention No specific preventive measures are known because of the idiosyncratic nature of these reactions. Patients must be monitored carefully to recognize the signs and symptoms, because promptly discontinuing the offending drug often leads to full recovery.[21]

Management Corticosteroid therapy is beneficial and should be initiated immediately or soon after diagnosis of AIN along with discontinuance of the offending drug to avoid the risk of incomplete recovery of renal function. While various regimens have been used, high-dose oral prednisone 1 mg/kg/day for 8 to 14 weeks with a stepwise taper has been used successfully.[111,115] Typical renal function indices (e.g., S_{cr}, BUN) and signs and symptoms of AIN should be monitored closely for improvement.

CHRONIC INTERSTITIAL NEPHRITIS

Lithium, analgesics, calcineurin inhibitors, aristolochic acid, and only a few other drugs have been reported to cause chronic interstitial nephritis, which is usually a progressive and irreversible lesion.[1,21]

Lithium

Incidence The prevalence of non-dialysis-dependent CKD stemming from chronic lithium nephrotoxicity in the general population of patients treated with lithium was recently estimated to be 1.2%.[117] The prevalence of lithium-induced ESRD among all ESRD patients is between 0.2% and 0.8%.[117,118] Several renal tubular lesions are associated with lithium therapy: an impaired ability to concentrate urine (nephrogenic diabetes insipidus) is seen in up to 87% of patients with biopsy proven nephrotoxicity,[113] and incomplete distal renal tubular acidosis is observed in up to 50% of these patients.[119]

Clinical Presentation Lithium-induced nephrotoxicity is typically asymptomatic and develops insidiously during years of therapy. Blood pressure is normal and urinary sediment is bland, making detection difficult until the disease progresses significantly.[120] It is usually recognized by rising BUN or S_{cr} concentrations or the onset of hypertension. Polydipsia (excessive thirst) and polyuria (excessive urination) are observed in 40% and 20%, respectively, of patients with nephrogenic diabetes insipidus (see Chap. 58).[119] Although interstitial fibrosis may be observed as early as 5 years after beginning therapy, lithium-induced CKD usually occurs after 10 to 20 years of lithium treatment.[120]

Pathogenesis The precise mechanism of chronic lithium-induced nephrotoxicity is not well characterized. Impaired ability to concentrate urine is a result of a decrease in collecting duct response to antidiuretic hormone, which may be related to downregulation of aquaporin 2 water channel expression during lithium therapy.[120] Chronic tubulointerstitial nephritis attributed to lithium is evidenced most commonly by biopsy findings of interstitial fibrosis, tubular atrophy, and glomerular sclerosis.[21,118] The pathogenesis may involve cumulative direct lithium toxicity since duration of therapy correlates with the decline in the GFR.

Risk Factors It is now established that long-term lithium therapy is associated with nephrotoxicity in the absence of episodes of acute intoxication, and that the duration of therapy is the major determinant of chronic nephrotoxicity.[118,120] Increased age may also be a risk factor, but daily dose is not.[120]

Prevention Prevention of acute and chronic toxicity includes maintaining lithium concentrations as low as therapeutically possible, avoiding dehydration, and monitoring renal function. It is unknown whether progression to CKD can be prevented by

stopping lithium use when mild kidney injury is first recognized. This poses a dilemma as lithium is highly effective for affective disorders and the risks and potential benefits of discontinuing such a beneficial drug need to be carefully considered.[120] However, if lithium therapy is continued, renal function must be monitored and therapy discontinued if it continues to decline. Amiloride has been used for prevention and treatment of lithium-induced nephrogenic diabetes insipidus, since it blocks epithelial sodium transport of lithium into the cortical collecting duct in the distal nephron.[120,121]

Management Symptomatic polyuria and polydipsia can be reversed by discontinuation of lithium therapy or ameliorated with amiloride 5 to 10 mg daily during continued lithium therapy (see Chap. 58).[119,121] If polyuria does not resolve within 7 to 10 days of therapy, then the amiloride dose should be increased to 20 mg daily. Progressive chronic interstitial nephritis is treated by discontinuation of lithium therapy, adequate hydration, and avoidance of other nephrotoxic agents. Lithium serum concentrations, as well as renal function indices, including urine output, BUN, and S_{cr}, should be monitored closely for resolution of signs and symptoms of toxicity.[120]

Cyclosporine and Tacrolimus

Delayed chronic tubulointerstitial nephritis, considered the Achilles' heel of calcineurin inhibitor based immunosuppressive regimens, has been reported after several months of therapy and can result in irreversible kidney disease.[82] Toxicity is progressive and usually manifests as a slowly rising S_{cr} concentration and decreased creatinine clearance that may not reflect the severity of histopathologic changes. All three compartments of the kidney can be affected, evidenced by typical biopsy findings that include arteriolar hyalinosis, glomerular sclerosis, and a striped pattern of tubulointerstitial fibrosis.[82,84,119] The pathogenesis appears to involve sustained renal arteriolar endothelial cell injury and increased extracellular matrix synthesis, which ultimately result in chronic ischemia of the tubulointerstitial compartment because of increased release of endothelin-1, decreased production of nitric acid, and upregulation of transforming growth factor-β.[82] Unlike acute nephrotoxicity, chronic toxicity is not dose dependent.

Aristolochic Acid

Incidence In the early 1990s, a cluster of young women with rapidly progressive kidney disease leading to ESRD were reported in Brussels, Belgium. The patients had strikingly similar pathologic findings of interstitial fibrosis with tubular atrophy on renal biopsy. Further investigation revealed that all the women were patients of the same weight-loss clinic and had received a weight-loss treatment containing Chinese herbs.[122] Subsequent analysis of the herb-based treatment demonstrated significant amounts of *Aristolochia fangchi* (Guang fang ji), known to contain aristolochic acid, the major alkaloid of the botanical species *Aristolochia*.[122] Although the true incidence is unknown, approximately 3% to 5% of patients who received the weight-loss regimen developed disease, and numerous additional cases of aristolochic acid nephropathy have been reported worldwide.[122]

Clinical Presentation Patients with aristolochic acid nephropathy typically present with mild to moderate hypertension, mild proteinuria, glucosuria, and moderately elevated S_{cr} concentrations.[122] Anemia and shrunken kidneys are also common on initial presentation. The overwhelming majority of cases reported to date have been in women. The main pathologic lesions observed in the kidneys are interstitial fibrosis with atrophy and destruction of proximal tubules throughout the renal cortex; in general, the glomeruli are not affected. Perhaps the most remarkable feature of aristolochic acid nephropathy is the rate at which it progresses. In most individuals, ESRD requiring dialysis or transplantation develops within 6 to 24 months of exposure. An alarming high prevalence (approximately 40% to 45%) of urothelial transitional cell carcinoma has been observed in Belgian patients who underwent renal transplantation.[122]

Pathogenesis Although the precise mechanism of aristolochic acid nephropathy and urothelial carcinoma has yet to be characterized. The major components of aristolochic acid are metabolized to mutagenic compounds called *aristolactam I* and *aristolactam II*, respectively, which have been demonstrated to form aristolochic acid–DNA adducts in humans. Recent data indicate that these adducts cause direct DNA damage and may lead to proximal tubular atrophy and apoptosis.[122]

Prevention The primary means of preventing aristolochic acid nephropathy appears to be the limitation of exposure to compounds containing aristolochic acids. Several countries, including the United Kingdom, Canada, Australia, and Germany, have banned the use of *Aristolochia*-containing herbs.[122]

PAPILLARY NECROSIS

Papillary necrosis is a form of chronic tubulointerstitial nephritis characterized by necrosis of the renal papillae, the regions of the kidney where the collecting ducts enter the renal pelvis, which leads to progressive kidney disease.[21,123] Papillary necrosis is associated with diabetes, sickle cell disease, obstruction and infection of the urinary tract, and most commonly analgesic use.[21,124]

Analgesic Nephropathy

Incidence Prototypical analgesic nephropathy is characterized by chronic tubulointerstitial nephritis with papillary necrosis.[21] Chronic excessive consumption of combination analgesics, particularly those containing phenacetin, was believed to be the major cause and led to the removal of phenacetin and phenacetin mixtures from most world markets. However, contemporary analgesics, particularly aspirin, acetaminophen, and NSAIDs, alone or in combination, are also associated with the development of analgesic nephropathy, but there is insufficient causative evidence to definitively link these nonphenacetin-containing analgesics with nephropathy.[123] The incidence of analgesic nephropathy has declined significantly since removal of phenacetin from many countries, with the prevalence estimated to now be <5% in the United States adult ESRD population.[124]

Clinical Presentation Analgesic nephropathy is a progressive disease that evolves slowly over several years.[124] It is difficult to recognize in the early stages of the disease because patients are often asymptomatic,[125] and it may be underdiagnosed as a cause of ESRD. It is seen more commonly in women than men.[21] Early manifestations are generally nonspecific and may include headache and upper gastrointestinal symptoms; later manifestations include impaired urinary concentrating ability, dysuria, sterile pyuria, microscopic hematuria, mild proteinuria (<1.5 g/day), and lower back pain. As disease progresses, hypertension, atherosclerotic cardiovascular disease, renal calculi, and bladder stones are common, and pyelonephritis is a classic finding in advanced analgesic nephropathy.[123,125] The most sensitive and specific diagnostic criteria include (1) a history of chronic daily habitual analgesic ingestion (daily use for at least 3 to 5 years); (2) intravenous pyelography, renal ultrasound, or renal computed tomography imaging, which reveals decreased renal mass and bumpy renal contours; (3) elevated S_{cr}, i.e., up to 4 mg/dL (354 μmol/L); and (4) papillary calcifications.[123,124]

Pathogenesis Analgesic nephropathy originates in the papillary tip as a result of accumulated toxins, drugs and metabolites,

decreased blood flow, and impaired cellular energy production. The metabolism of phenacetin to acetaminophen, which is then oxidized to toxic free radicals that are concentrated in the papilla, appears to be the initiating factor that causes toxicity by mechanisms analogous to acetaminophen hepatotoxicity via glutathione depletion.[21,119] Cortical interstitial nephritis develops secondary to papillary necrosis. Salicylates potentiate these effects by also depleting renal glutathione, and inhibiting prostaglandin-mediated vasodilation, thus further predisposing the renal medulla to ischemic injury.[21,119]

Risk Factors The epidemiology of analgesic use and analgesic nephropathy continues to evolve. The classic concept persists that risk for ESRD increases with cumulative consumption of combination analgesics, phenacetin, or acetaminophen and aspirin or NSAIDs. Caffeine contained in combination analgesics may increase risk, but the role is not clear.[123,124] Chronic use of therapeutic doses of NSAIDs alone, but not aspirin or salicylates alone, can cause analgesic nephropathy. High-dose acetaminophen use alone is associated with an increased risk for ESRD. However, these associations remain inconclusive as a consequence of study design flaws, as acetaminophen has been the preferentially prescribed analgesic for patients with chronic kidney disease.[123,124]

Prevention Prevention has depended primarily on public health efforts to restrict the sale of phenacetin and combination analgesics. This has effectively reduced analgesic nephropathy in Australia and Europe.[123] However, risk continues with ongoing availability of nonprescription combination analgesics containing aspirin, acetaminophen, and caffeine in the United States and throughout the world.

Individuals requiring chronic analgesic therapy may reduce risk by limiting the total dose, avoiding combined use of two or more analgesics, and maintaining good hydration to prevent renal ischemia and decrease the papillary concentration of toxic substances. Acetaminophen remains the preferred nonopiate analgesic for patients with preexisting kidney disease.

Management Treatment of established nephrotoxicity requires cessation of analgesic consumption.[119] This can prevent progression and may improve renal function. Renal function indices, including urine output, BUN, and S_{cr}, should be monitored every several months. Patients should also be monitored for the development of transitional cell carcinoma of the renal pelvis, calyces, ureters, and bladder, which may present years after analgesic nephropathy is diagnosed.[21]

RENAL VASCULITIS, THROMBOSIS, AND CHOLESTEROL EMBOLI

RENAL VASCULITIS

Drug-induced renal vascular disease commonly presents as vasculitis, thrombotic microangiopathy, or cholesterol emboli. Vasculitis implies inflammation of the vessel wall, capillaries, or glomeruli and is typically classified according to vessel size (i.e., small, medium, or large vessel vasculitis).[25] Small vessel vasculitides usually affect multiple organ systems, including the kidneys and lungs, and are associated with nonspecific inflammatory symptoms such as fever, malaise, myalgias, arthralgias, and weight loss.[105] Numerous drugs are associated with the development of renal vasculitis, including hydralazine, propylthiouracil, allopurinol, phenytoin, sulfasalazine, penicillamine, and minocycline (Table 55–1).[25,126] Most drug-induced cases of vasculitis, including hydralazine, propylthiouracil, allopurinol, and penicillamine, have been implicated in the development of antineutrophil cytoplasmic antibody (ANCA)-positive vasculitis.[25,127] Recently, the antitumor necrosis factor-α drug adalimumab was associated with the development of ANCA-associated renal vasculitis.[126,128] Patients present with hematuria, proteinuria, oliguria, and red cell casts, frequently along with fever, malaise, myalgias, and arthralgias.[25,105] Treatment typically consists of withdrawing the offending drug and administration of corticosteroids or other immunosuppressive therapy, and usually leads to resolution of symptoms within weeks to months.[126]

Thrombotic Microangiopathy

Thrombotic microangiopathy is characterized clinically by microangiopathic hemolytic anemia, fragmented red cells, and thrombocytopenia and pathologically by vascular endothelial proliferation, endothelial cell swelling, and intraluminal platelet thrombi in the small vessels, particularly affecting the renal and cerebral capillaries and arterioles.[24,25,129] The absence of inflammation in vessel walls distinguishes thrombotic microangiopathy from vasculitis. Numerous medications, including oral contraceptive agents, cyclosporine, tacrolimus, muromonab-CD3, many cancer chemotherapeutic agents including mitomycin C, cisplatin, and gemcitabine, interferon-α, ticlopidine, clopidogrel, and quinine are associated with the development of thrombotic microangiopathy.[24,25,129] Recently, bevacizumab, a humanized monoclonal antibody against vascular endothelial growth factor, was reported to cause thrombotic microangiopathy,[130] and other drugs in the class have also been implicated in vascular adverse reactions.[131] Patients may present with fever, neurological dysfunction, elevated S_{cr} and BUN, and hypertension, along with microangiopathic hemolytic anemia and thrombocytopenia.[25] Kidney injury can be severe and irreversible, although corticosteroids, antiplatelet agents, plasma exchange, plasmapheresis, and high-dose intravenous immunoglobulin G have each induced clinical improvement.

Cholesterol Emboli

Anticoagulants (particularly warfarin) and thrombolytics (e.g., urokinase, streptokinase, tissue-plasminogen activator) are associated with cholesterol embolization of the kidney.[1,132] These drugs act to remove or prevent thrombus formation over ulcerative plaques or may induce hemorrhage within clots, thereby causing showers of cholesterol crystals that lodge in small diameter arteries of the kidney (renal arterioles and glomerular capillaries). Cholesterol crystal emboli induce an endothelial inflammatory response, which leads to complete obstruction, ischemia, and necrosis of affected vessels within weeks to months after initiation of therapy.[1,132] Purple discoloration of the toes and mottled skin over the legs are important clinical clues. Treatment is supportive in nature, since kidney injury is generally irreversible.

COSTS OF DRUG-INDUCED KIDNEY DISEASE

The costs of DIKD are not well defined, but recent data indicate that the pharmacoeconomic implications are enormous. An increase in S_{cr} of ≥0.5 mg/dL (44 μmol/L) is independently associated with a 6.5-fold increase in the odds of death, a 3.5-day increase in length of hospital stay, and nearly $7,500 in excess hospital costs even after adjusting for age, sex, and measures of comorbidity.[9] A recent report indicates that amphotericin B-induced AKI leads to a mean increased length of hospital stay of 8.2 days and adjusted additional costs of $29,823 per patient.[133] Lastly, the mean additional in-hospital cost for each episode of contrast-induced AKI has been estimated to be $10,345 per case. The major driver of the increased costs associated with contrast-induced AKI was the cost of the

longer initial hospital stay.[34] The increased availability of automated clinical decision support systems and computer-guided medication dosing for hospital inpatients may improve the safety of potentially harmful drugs and minimize the occurrence of nephrotoxicity in this setting, thereby potentially lowering the corresponding economic consequences.[133]

ABBREVIATIONS

ACEI: angiotensin-converting enzyme inhibitor

AIDS: acquired immune deficiency syndrome

AIN: allergic interstitial nephritis

AKI: acute kidney injury

ARB: angiotensin II receptor blocker

BUN: blood urea nitrogen

CIN: contrast media-induced nephrotoxicity

CKD: chronic kidney disease

COX: cyclooxygenase

CYP: cytochrome P450

ESRD: end-stage renal disease

FSGS: focal segmental glomerulosclerosis

GFR: glomerular filtration rate

HIV: human immunodeficiency virus

KIM-1: kidney injury molecule-1

NGAL: neutrophil gelatinase-associated lipocalin

NSAID: nonsteroidal antiinflammatory drug

OSPS: oral sodium phosphate solution

S_{cr}: serum creatinine

CHAPTER 56

Glomerulonephritis

ALAN H. LAU

KEY CONCEPTS

1. Glomerulonephritis is a collection of glomerular diseases mediated by different immunologic pathogenic mechanisms, resulting in varied clinical presentation and therapeutic outcomes.
2. The signs and symptoms associated with glomerulonephritis can be nephritic in nature, characterized by inflammatory injury, or nephrotic in nature, characterized by proteinuria.
3. In the absence of specific and effective therapy for many types of glomerulonephritis, supportive treatments for edema, hypertension, hyperlipidemia, and intravascular thrombosis play important roles in reducing the complications associated with the disease.
4. To maximize therapeutic benefits and minimize drug-induced complications, patients have to be monitored closely to assess their therapeutic responses as well as the development of any treatment-induced toxicities.
5. Among all the types of glomerulonephritis, minimal-change nephropathy is most responsive to treatment. Steroids can induce good responses in most patients during initial treatment as well as relapse.
6. Because of the lack of consistently effective treatment for primary focal segmental glomerular sclerosis, angiotensin-converting enzyme inhibitors or angiotensin receptor blockers are commonly used for patients with mild disease to control symptoms. Steroids and immunosuppressive agents are reserved for patients with severe disease.
7. The optimal treatment for lupus nephritis depends on the underlying lesion and disease activity, as well as the severity and duration of the clinical presentation.
8. The treatment of poststreptococcal glomerulonephritis is mainly supportive and symptomatic. Antibiotic therapy does not prevent subsequent diseases but may reduce the severity.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

The precise pathogenetic mechanisms of many glomerular diseases remain unknown, and the available therapeutic regimens are still far from optimal. This chapter provides an overview of the primary causes of glomerulonephritis with a focus on their etiology, the pathophysiologic mechanisms responsible for glomerular injury, and the clinical presentation of the eight predominant types of glomerulonephritis. Treatment options and monitoring approaches for each of these types of glomerulonephritis are also discussed. Diabetes mellitus is an important secondary cause of glomerular injury, and a thorough discussion of the pathophysiology and management of this condition can be found in Chap. 83.

NORMAL GLOMERULAR ANATOMY AND FUNCTION

The glomerulus, which is enclosed within the Bowman capsule, consists of two important components: the filtration barrier and the mesangium (Fig. 56–1). The capillary wall, which serves as a filtration barrier, consists of three well-defined layers: fenestrated endothelium, glomerular basement membrane (GBM), and epithelial cell layer. The epithelial cells, also known as podocytes, have specialized foot processes embedded in the outer layer of the GBM. It is across this barrier that fluid flows and ultimately becomes the ultrafiltrate. Under normal conditions, the GBM functions as a compact hydrated gel of matrix proteins with a pore-like structure. The mesangium, which consists of mesangial cells embedded in an extracellular matrix, provides support for the glomerular capillaries and also modulates blood flow through the capillaries.

The unique capillary bed of the glomerulus allows small nonprotein plasma constituents up to the size of inulin, which has a molecular weight of 5.2 kDa, to pass freely while excluding macromolecules equal to or larger than albumin, which has a molecular weight of 69 kDa. The ease of passage of solutes through the glomerular membrane is impacted by both the size and charge of the solute. Fixed,

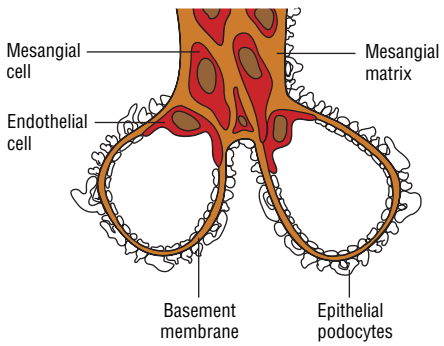

FIGURE 56-1. Microanatomy of the glomerulus.

negatively charged sites are found within the glomeruli in all three layers of the capillary wall: the endothelium, the epithelium, and the GBM. The movement of negatively charged molecules is thus restricted more than that of neutral or positively charged molecules. Different glomerular diseases affect this size- and charge-selective barrier to different extents; consequently, glomerulopathies present with varied clinical features and solute-excretion patterns.

Some of the glomerular cells, such as the epithelial cells, have phagocytic function that can remove macromolecules trapped within the filtration barrier. They are also capable of synthesizing the GBM. In contrast, the mesangial cells regulate glomerular hemodynamics in response to angiotensin II and by producing prostaglandins. These cells also synthesize and respond to various cytokines and thus play a key role in immune-mediated glomerular diseases. Resident phagocytes in the mesangium are responsible for moving macromolecules trapped in the basement membrane into the urinary space. They are also involved in the development of both immune and nonimmune glomerular injury.

EPIDEMIOLOGY AND ETIOLOGY

In the United States in 2007, glomerulonephritis was the third most common cause of end-stage renal disease (ESRD), accounting for approximately 15% of all the living ESRD patients. About 7,500 patients (6.8% of all patients) develop stage 5 chronic kidney disease, which is also called end-stage renal disease (ESRD), because of glomerulonephritis each year.[1]

Humoral and cellular immunologic mechanisms participate in the pathogenesis of most glomerulonephritis. Abnormalities in coagulation and metabolism, as well as hereditary and vascular diseases, also contribute to glomerular damage. The histopathologic manifestations vary substantially among the different types of glomerulonephritis. An overview of the primary pathogenetic mechanisms is presented in this section, and specific abnormalities for each of the primary types of glomerulonephritis are presented in subsequent sections.

PATHOPHYSIOLOGY

1 The glomerular lesion may be diffuse (involving all glomeruli), focal (involving some but not all glomeruli), or segmental, also known as local (involving part of the individual glomerulus). The pathologic manifestations may also be described as proliferative (overgrowth of epithelium, endothelium, or mesangium), membranous (thickening of GBM), and/or sclerotic.

The glomerular capillary wall is particularly susceptible to immune-mediated injury. Antigen and antibody tend to localize in the glomerulus, probably because of its high blood flow and capillary hydrostatic pressure. Parenchymal damage can be induced as a result of humoral- and cell-mediated immune reactions (Table 56–1). Antibodies and sensitized T lymphocytes are the primary mediators of glomerular injury.[2,3]

Production of antibodies to endogenous or exogenous antigens that are recognized as foreign by the host is the first step in humoral immunologic damage to the glomerulus. Endogenous antigens may be intrinsic glomerular antigens, such as Heymann antigen on the epithelial cell or Goodpasture antigen on the GBM, or previously sequestered antigens, such as DNA or thyroglobulin. Exogenous antigens are most often viral, bacterial, parasitic, or fungal in origin. Antineutrophil cytoplasmic autoantibodies (ANCAs) (i.e., autoantibodies that react to the cytoplasmic components of neutrophils and monocytes) are found in patients with idiopathic crescentic glomerulonephritis and also in the accompanying vasculitis.

Complexes of antigens and antibodies may be formed in the circulation and then passively entrapped in the glomerular capillary or mesangium. Alternately, experimental antibodies may combine with endogenous glomerular antigens or exogenous antigens entrapped in the glomerulus to form complexes locally, or in situ.[3] The type and extent of glomerular damage are dependent on the location of the immune complex formation and the rate at which it is removed. Impaired removal facilitates the growth of the complex and thus increases the likelihood of glomerular damage.

Subsequent to antigen–antibody formation, a series of biologic events is triggered that ultimately leads to glomerular injury. Noninflammatory lesions can result from the binding of noncomplement-fixing antibody to the glomerular epithelial cell (mechanism 1) or from the activation of the complement system to form the C5b-9 membrane attack complex (mechanism 2).[3] Both mechanisms can damage the glomerular epithelial cell and result in capillary wall injury and proteinuria. Inflammatory lesions are induced by glomerular infiltration of circulating inflammatory cells such as neutrophils, monocytes/macrophages, and platelets (mechanism 3) or by proliferation of resident glomerular mesangial cells (mechanism 4), resulting in GBM damage.[3] The migration of neutrophils and monocytes to the glomerular tufts is promoted by chemoattractants such as complement fragments (C3a and C5a), platelet-activating factor, interleukin-8, and monocyte chemotactic protein-1.[4] Various cytokines, chemokines, and growth factors are then released to participate in the inflammatory process.[2]

T cells sensitized to glomerular antigen, macrophages, and resident mesangial cells are important participants in cell-mediated injury. Sensitized T cells can cause glomerular hypercellularity in the absence of antibody deposition.[2–4] Cytotoxic T cells may bind with the target cells and destroy them. Alternatively, a delayed-type hypersensitivity reaction may be initiated by activated T cells through the release of lymphokines to attract, activate, and transform monocytes into macrophages.[3] These humoral and cellular mediators, in conjunction with a host of toxic molecular entities including reactive oxygen species, proteinases, eicosanoids, and procoagulants, which are secreted by neutrophils, macrophages, platelets, and resident glomerular cells can alter the permeability, blood flow, and function of the glomeruli. Vascular constriction and occlusion follow and result in the eventual destruction of the glomeruli.

Acute forms of glomerular injury frequently lead to chronic and persistent renal dysfunction, even though the original immune factors that induced the initial glomerular injury have resolved. Experimental and clinical investigations suggest that a variety of factors may participate in the progression of renal injury. These factors include systemic and glomerular hypertension, high dietary protein intake, proteinuria, glomerular hypertrophy, hyperlipidemia, activation of the coagulation system, abnormalities of calcium and phosphorus balance, and tubulointerstitial injury. The degree of proteinuria not only is an index of the severity of glomerular disease but also has been associated with an increased the rate of progression of renal injury. Heavy

[a]Can be immune complex-mediated, antiglomerular basement membrane antibody-mediated, or associated with antineutrophil cytoplasmic autoantibodies.

proteinuria is an indicator of poor prognosis in various glomerular diseases.

Proteinuria is also accompanied by an increased flux of macromolecules across the mesangium. The mesangial overload may then lead to structural damage. The passage of serum components, such as complement, across the GBM may have a pathophysiologic effect on the glomerular epithelial cells and alter the integrity of the glomerular filtration barrier. The damaging effects of macromolecules other than albumin, such as immunoglobulins, lipoproteins, transferrin, and complement, remain to be characterized.

CLINICAL PRESENTATION

2 Although patients with glomerular disease may present with an array of signs and symptoms, they are often categorized into one of two broad classifications: nephritic syndrome or nephrotic syndrome (Table 56–2). The unique clinical presentation characteristics of the predominant glomerulopathies are described in the individual disease sections, presented later in the chapter.

Nephritic syndrome reflects glomerular inflammation and frequently results in hematuria. White cells and cellular and granular casts are commonly found in the urine. In contrast, nephrotic syndrome reflects noninflammatory injury to the glomerular structures and results in few cells or cellular casts in the urine. Initially, there may be limited or no reduction in renal excretory function.

Hematuria occurs when red blood cells leak through the openings of the GBM. The presence of red cell casts is highly indicative of glomerulonephritis or vasculitis. The presence of dysmorphic red blood cells in the urine is suggestive of glomerular disease. The red blood cells are damaged as they pass through the openings in the GBM or the cells may sustain osmotic injury as they travel through the different osmotic environments within the lumen of the kidney tubules.

The presence of proteinuria indicates a defect of the size- and/or charge-selective barriers within the GBM. Normal urinary protein excretion is between 40 and 80 mg/day, with a maximum of 150 mg. Fewer than 20 mg of the excreted proteins are albumin. Most of the albumin that enters the glomerular filtrate is either reabsorbed or catabolized by the tubular epithelium. The dipsticks that are commonly used to identify proteinuria detect only albumin; they become positive when protein excretion is more than 300 to 500 mg/day. They are therefore unable to detect the early stages of renal injury secondary to diabetes mellitus or hypertension, which often result in microalbuminuria with urinary albumin excretion ranges between 30 and 300 mg/day. Chemstrip Micral-Test II (Roche Diagnostics, Indianapolis, IN), a simple immunoassay on a dipstick, permits specific and semiquantitative determination of urinary albumin concentrations at five levels: 0, 10, 20, 50, and 100 mg/L. Another qualitative test, Micro-Bumintest (Bayer Diabetes Care, Mishawaka, IN), registers a positive reading when the urine albumin concentration is greater than 40 mg/L.

Hypertension is common for patients with glomerular diseases, as a result of renal salt retention causing plasma volume expansion. In contrast, increased activity of vasoconstrictors such as angiotensin II is often the cause for patients with chronic glomerular diseases. Scarring of the glomerulus resulting in regional ischemia is thought to be responsible for the hypertension. Activation of the sympathetic nervous system and the release of vasoconstrictor substances may also contribute.

NEPHRITIC SYNDROME

Glomerular bleeding resulting in hematuria is typical in nephritic syndrome. Dysmorphic red cells, especially acanthocytes, are a sensitive and specific marker of glomerular bleeding. The presence of pus and cellular and granular casts in the urine is common. The extent of proteinuria is variable. Patients with severe nephritic glomerular injury have renal function impairment because of the reduced glomerular surface area available for filtration, as a result of constriction of the capillary lumen by proliferating mesangial cells or inflammatory cells.

CLINICAL PRESENTATIONS OF NEPHRITIC AND NEPHROTIC SYNDROMES

General

- The patients are generally not in acute distress

Symptoms

- The patients may not experience any major symptoms

Nephritic Signs	Nephrotic Signs
Hematuria	Edema
Hypertension and edema as renal function declines	Weight gain
	Fatigue
Laboratory Tests	
Proteinuria up to 3 g/day	Proteinuria, >3.5 g/day/1.73 m^2
Pus, cellular and granular casts in urine is common	Hyperlipidemia
Hypoproteinemia	Lipiduria
Hypercoagulable state for some patients	

NEPHROTIC SYNDROME

Nephrotic syndrome is characterized by proteinuria greater than 3.5 g/day per 1.73 m^2, hypoproteinemia, edema, and hyperlipidemia. A hypercoagulable state may also be present in some patients. The syndrome may be the result of primary diseases of the glomerulus, or be associated with systemic diseases such as diabetes mellitus, lupus, amyloidosis, and preeclampsia. Hypoproteinemia, especially hypoalbuminemia, results from increased urinary loss of albumin and an increased rate of catabolism of filtered albumin by proximal tubular cells. The compensatory increase in hepatic synthesis of albumin is insufficient to replenish the protein loss, probably because of malnutrition.

Edema formation in patients with nephrotic syndrome was traditionally thought to be driven by the reduced plasma oncotic pressure secondary to hypoalbuminemia. If the oncotic pressure is low, the movement of fluid from the vascular space to the interstitial compartment results in a reduction of the plasma volume, which can trigger compensatory renal sodium and water retention through the activation of the renin–angiotensin–aldosterone axis, vasopressin, and the sympathetic nervous system (the "underfill" mechanism). However, experimental data reveal that the plasma volume is actually normal or elevated. Hypoalbuminemia may not cause edema until the serum albumin concentration is less than 2 g/dL (20 g/L). In addition, the transcapillary oncotic pressure gradient is not as high as previously thought because increased lymphatic flow reduces the interstitial oncotic pressure by removing protein and fluid from the interstitium, thereby reducing the transcapillary oncotic pressure gradient.[5] Instead, fluid retention is likely mediated by a primary increase in sodium reabsorption at the distal nephron, which is probably caused by tubular resistance to the action of atrial natriuretic peptide (the "overflow" mechanism).[6] It is likely that both mechanisms may contribute to nephrotic edema in different patients.[6]

Albuminuria greater than 3 g daily is associated with a significant increase in serum cholesterol concentrations for patients with primary glomerular disease.[7] Hyperlipidemia in nephrotic syndrome is characterized by elevated serum total cholesterol and triglyceride concentrations, with increased very-low-density lipoprotein (VLDL) and low-density lipoprotein (LDL) cholesterol concentrations. Lipoprotein (a) levels may also be increased. The reduced plasma oncotic pressure as a result of hypoalbuminemia may stimulate hepatic synthesis of lipids and lipoproteins. The increased VLDL production and increased liver cholesterol synthesis, along with a decrease in LDL receptor activity, can then lead to an increase in LDL cholesterol concentrations. In addition, reduced serum albumin or the loss of a liporegulatory substance may result in reduced VLDL clearance.[8] Nephrotic patients with hyperlipidemia, especially those with concomitant hypertension, are presumed to have an increased risk for atherosclerotic vascular disease. Hyperlipidemia also promotes the progression of glomerular injury, as evidenced by glomerulosclerosis, mesangial expansion, and hyalinosis.[8,9]

Many patients with nephrotic syndrome have a hypercoagulable state caused by defects of several control proteins in the coagulation cascade. The concentration of the coagulation inhibitor antithrombin III is reduced because of increased loss in the urine. A reduced amount of the coagulation inhibitors proteins C and S, along with increased concentrations of factors V and VIII, increased fibrinogen concentrations and abnormal platelet function, may also contribute to the hypercoagulable state. The net result of these alterations in coagulation is an increased risk for arterial and venous thrombosis, especially in the deep veins and renal veins. As many as 25% of patients with membranous nephropathy may have renal vein thrombosis.

DIAGNOSIS

Patients with suspected glomerular disease should have an extensive medical history obtained to identify potential systemic causes (Table 56–3). Medication, environmental, and occupational histories may also help identify possible exposure to potentially nephrotoxic agents. A carefully conducted physical examination and laboratory evaluation may reveal the presence of systemic diseases that may contribute to the development of glomerular disease (Fig. 56–2). In addition, the patient's age, gender, and ethnic background may be helpful in pinpointing the specific type of glomerular disease. Many of the conditions are more prevalent in certain age groups, although they may occur at any age. For example, proliferative glomerulonephritis is more common in those younger than 40 years of age, whereas the incidence of membranous glomerulonephritis is dramatically higher in those older than 50 years of age.

TABLE 56-3 Evaluation of Patients Suspected of Having Glomerular Disease

Medical history

To identify symptoms of medical conditions that may cause glomerular disease
- Diabetes mellitus
- Amyloidosis
- Systemic lupus erythematosus
- Other familial conditions associated with renal disease

To identify symptoms suggestive of nephrotic syndrome
- Reduced appetite
- Fatigue
- Weight gain
- Edema

Medication, environmental, and occupational histories

To identify possible exposure to potentially nephrotoxic drugs, toxins, or chemicals

Physical examination

To identify signs and symptoms associated with systemic diseases
- Hypertension
- Rash
- Arthritis
- Retinopathy
- Neuropathy
- Lymphadenopathy
- Hepatomegaly
- Malignancy

Laboratory evaluation

Urinalysis
- To determine nephrotic nature of glomerular disease
  - Proteinuria, >3.5 g/day/1.73 m^2
  - Lipiduria
- To determine nephritic nature of glomerular disease
  - Hematuria
  - Pyuria
  - Cellular, granular casts

Glomerular filtration rate
- To determine extent of glomerular damage

Other tests
- To identify type and etiology of glomerular disease
  - Serum complement concentration
  - Antinuclear and anti-DNA antibodies
  - Antistreptolysin antibodies
  - Circulating antiglomerular basement membrane antibodies
  - Cryoglobulins

Percutaneous renal biopsy
- To provide definitive diagnosis of glomerular disease

Laboratory evaluation such as urinalysis can help differentiate the nephrotic or nephritic nature of the disease. The glomerular filtration rate (GFR) may be used to determine the extent of glomerular damage. In the early stages of the disease, the GFR may remain normal. Initial injury to the glomerulus primarily lowers the permeability coefficient (K_f) of the GBM by reducing the surface area available for filtration and/or the unit permeability of the membrane. The reduced permeability is compensated by an elevation in the glomerular capillary hydrostatic pressure through afferent arteriolar dilation and efferent arteriolar constriction. Extensive glomerular damage may therefore be present before a substantial reduction of total GFR is evident.

Although the cause of glomerular disease may be established from clinical and laboratory evaluation, sometimes percutaneous renal biopsy may be needed to provide a definitive diagnosis.

TREATMENT

Glomerulonephritis

GENERAL APPROACH TO TREATMENT

The management of patients with glomerulonephritis involves specific pharmacologic therapy for the glomerular disease and supportive measures to prevent and/or treat the pathophysiologic sequelae, namely, hypertension, edema, and progression of renal disease. For patients with nephrotic syndrome, supportive therapy should also address the management of extrarenal complications of heavy proteinuria, namely, hypoalbuminemia, hyperlipidemia, and thromboembolism. Because patients with significant proteinuria tend to have more rapid decline of renal function, reduction of proteinuria thus becomes critical in delaying the rate of progression toward ESRD.

Immunosuppressive agents, alone or in combination, are commonly used to alter the immune processes that are responsible for the glomerulonephritides. Corticosteroids, in addition to their immunosuppressive effect, also possess antiinflammatory activities. They reduce the production and/or release of many substances that mediate the inflammatory process, such as prostaglandins, leukotrienes, platelet-activating factors, tumor necrosis factors, and interleukin-1 (IL-1). Movement of leukocytes and macrophages to the site of inflammation is also inhibited. The immunosuppressive effects of corticosteroids are mediated through the inhibition of the release of IL-1 and tumor necrosis factor by activated macrophages, and interleukin-2 (IL-2) by activated T cells. In addition, the actions of migration-inhibiting factor and γ-interferon are inhibited. Processing of antigens is thus affected by the presence of corticosteroids. Cytotoxic agents, such as cyclophosphamide, chlorambucil, or azathioprine, are commonly used to treat glomerular diseases. Cyclosporine can reduce lymphokine production by activated T lymphocytes, and it may decrease proteinuria by improving the permselectivity of the GBM. Mycophenolate mofetil is useful in different glomerulonephritides because of its effects on T- and B-cell lymphocytes.

Because many immune factors are implicated in the pathogenesis of glomerulonephritis, plasmapheresis may be used to remove these mediators. During the procedure, whole blood is removed from the body and centrifugation is used to separate the cellular elements from the plasma. The cells are then infused back to the patient after resuspension in saline or plasma substitute. The plasma proteins, presumably including the pathogenic immune factors, are thereby removed from the patient.

Recently, many novel targets were identified and new agents are being evaluated for their usefulness to control the disease, preserve renal function, and improve patient outcome. To stay abreast of the expanding availability of treatment options, one can routinely consult one of the clinical trial registries, such as *www.clinicaltrials.gov*.[10]

SUPPORTIVE THERAPY

3 For patients with nephrotic syndrome, dietary measures involve restriction of sodium intake to 50 to 100 mEq/day (50 to 100 mmol/day),[11] protein intake of 0.8 to 1 g/day,[11,12] and a low-lipid diet of less than 200 mg cholesterol. Total fat should account for less than 30% of daily total calories.[11] Sodium restriction is important not only in the control of edema, but also in the control of hypertension and proteinuria. Similarly, protein restriction not only helps to reduce proteinuria but also has a potential role in retarding the progression of renal disease. Patients should also stop smoking because a dose-dependent increase in risk for developing ESRD was observed in men with primary inflammatory (immunoglobulin A glomerulonephritis) or noninflammatory (polycystic kidney disease) renal diseases.[13]

Edema

Management of nephrotic edema involves salt restriction, bedrest, and use of support stockings and diuretics. However, severe salt restriction is difficult to achieve and prolonged bedrest could predispose nephrotic patients to thromboembolism. Hence the use of a loop diuretic such as furosemide is frequently required. Although the delivery of diuretic to the kidney tubules is normal, the presence of large amounts of protein in the urine promotes drug binding, and thereby reduces the availability of the diuretic to the luminal receptor sites. In addition, reduced sodium delivery to the distal tubule secondary to decreased glomerular perfusion may also alter diuretic effectiveness. Large doses of the loop diuretic, such as 160 to 480 mg of furosemide, may be needed for patients with moderate edema (see Chap. 58). In some instances, a thiazide diuretic or metolazone may be added to enhance natriuresis.[11,14] Alternatively, continuous intravenous infusion of a loop diuretic, such as furosemide 160 to 480 mg/day, may be employed.[15] For patients with morbid edema, albumin infusion may be used to expand plasma volume and to increase diuretic delivery to the renal tubules, thus enhancing diuretic effect. However, it may precipitate congestive heart failure and may also reduce therapeutic response to steroid in minimal-change nephropathy. For patients with significant edema, the goal of treatment should be a daily loss of 1 to 2 lb (0.45 to 0.9 kg) of fluid until the patient's desired weight has been obtained.

Hypertension

Optimal control of hypertension for patients with glomerular disease is important in reducing both the progression of renal disease and the risk for cardiovascular disease[12] (see Chaps. 19 and 52). The target blood pressure for patients with chronic kidney disease defined by GFR <60 mL/min (<1.0 mL/s) or albuminuria >300 mg/day is less than 130/80 mm Hg.[16] Angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin II receptor blockers (ARBs) delay the loss of renal function for patients with diabetic and nondiabetic (primarily glomerulonephritis) renal diseases.[17] Nondihydropyridine calcium channel blockers (e.g., diltiazem, verapamil) reduce proteinuria and preserve renal function and could be used as an additional agent. In contrast, the dihydropyridine calcium channel blockers (e.g., nifedipine, amlodipine, or nisoldipine) are effective in lowering blood pressure, but without the benefit of proteinuria reduction.[18]

Proteinuria

Dietary protein restriction reduces proteinuria and may retard renal function deterioration. Secondary analysis of the Modification of Diet in Renal Disease Study for patients with moderate renal insufficiency [GFR of 25 to 55 mL/min/1.73 m^2 (0.24 to 0.53 mL/s/m^2)] revealed that reduced protein intake (0.66 g/kg/day) delayed the rate of GFR deterioration for patients with severe renal insufficiency [GFR of 13 to 24 mL/min/1.73 m^2 (0.13 to 0.23 mL/s/m^2)].[19] Consequently, modest protein restriction of 0.8 g/kg/day is reasonable for patients with moderate renal insufficiency. Decreasing dietary protein also reduces the intake of phosphorus and potassium. In many instances, the potential benefits of protein restriction have to be balanced against the need for protein intake to overcome nutritional deficiencies. For nondialyzed patients who have GFRs of less than 25 mL/min/1.73 m^2 (0.24 mL/s/m^2), dietary protein intake should be reduced to 0.6 g/kg/day.[12]

It is now recognized that proteinuria is an independent risk factor for renal function decline and cardiovascular disease.[20] Reducing proteinuria can retard renal function loss and delay the progression to ESRD.[21] The antiproteinuric effect of ACEIs is associated with a fall in filtration fraction, suggesting a reduction in intraglomerular pressure. Recent studies show that ACEIs and ARBs may also have direct effects on podocytes, resulting in reduction of proteinuria and glomerular scarring. [22] In addition, angiotensin-converting enzyme (ACE) inhibition may also reduce the effect of angiotensin II on renal cell proliferation, thereby reducing sclerosis. These beneficial effects on proteinuria are beyond what can be attributed by the drug's antihypertensive effects (see Chap. 52).[23,24]

CLINICAL CONTROVERSY

Are there differences in the proteinuria reduction and renal protective effects of ACEIs and ARBs? Would combined use of the agents be justified?

The combined use of an ACEI and an ARB reduces the rate of renal function decline more than either treatment alone.[17] A meta-analysis of 21 randomized, controlled studies revealed that combination therapy enhanced the reduction of proteinuria in both diabetic and nondiabetic patients.[25] Combination therapy maximizes blockade of the renin–angiotensin system by counteracting the effects of angiotensin II produced by non-ACE pathways. In addition, with the blockade of the angiotensin II type 1 receptor, the angiotensin II produced by the non-ACE pathways may still act on the angiotensin II type 2 receptors, further facilitating vasodilation.[26] An angiotensin II receptor antagonist should therefore be added to the regimen for those patients who do not attain full and persistent remission of proteinuria with an ACEI alone.

Nonsteroidal antiinflammatory drugs (NSAIDs) probably reduce proteinuria through prostaglandin E_2 inhibition, resulting in a reduction of intraglomerular pressure, a decrease in GFR, and restoration of the barrier size selectivity of the GBM.[11] Indomethacin and meclofenamate are the two most evaluated NSAIDs. Their antiproteinuric effect is comparable to that attained with ACEIs, and combined treatment with an ACEI results in additional proteinuria reduction.[27] However, adherence to a low-sodium diet or concurrent use of a diuretic is needed to maximize the antiproteinuric effect. Because of their potential for nephrotoxicity, especially for patients with poor renal function, long-term use of an NSAID for renoprotection is not preferred.[23]

Hyperlipidemia

An abnormal lipoprotein profile increases the risk of atherosclerosis and coronary heart disease for patients with nephrotic syndrome. It is therefore important to treat patients with persistent nephrotic syndrome and sustained dyslipidemia, especially those with high VLDL and LDL cholesterol levels in the presence of a normal or low high-density lipoprotein cholesterol level (see Chaps. 28 and 53). Therapy is especially needed for those with concurrent atherosclerotic cardiovascular disease, or with additional risk factors for atherosclerosis, such as smoking and hypertension.[8]

A low-fat diet is usually not sufficient to correct hyperlipoproteinemia.[11] β-Hydroxy-β-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors, also known as "statins" such as lovastatin, pravastatin, simvastatin, and fluvastatin, are considered the treatment of choice.[11] They reduce total plasma cholesterol concentration, LDL cholesterol, and total plasma triglyceride concentrations.[8] Aside from the lipid-lowering effects, statins may confer renoprotection through different mechanisms, including reduction of cell proliferation and mesangial matrix accumulation and antiinflammatory and immunomodulatory effects.[28] Recent clinical studies show that they can reduce proteinuria and delay renal function loss.[29,30] The combined use of an ACEI with a statin may offer additional benefits in controlling nephrotic hyperlipidemia.[19]

Anticoagulation

Renal vein thrombosis, pulmonary emboli, or other thromboembolic events, are serious and common complications of nephrotic syndrome, and are frequently seen in those with membranous nephropathy. Although patients who have documented thromboembolic episodes should be anticoagulated with warfarin until remission of nephrotic syndrome, the use of prophylactic anticoagulation is controversial. A decision analysis study suggested that prophylactic anticoagulation is beneficial for patients with membranous nephropathy.[31] Prophylactic anticoagulation is not recommended for all patients, rather a "selective" approach or individualized assessment should be conducted to identify those at high risk [i.e., those with severe nephrotic syndrome and a serum albumin concentration <2.0 to 2.5 g/dL (<20 to 25 g/L)].[31] Also at risk are those who require prolonged bedrest, those receiving high-dose intravenous steroid therapy, and individuals who are dehydrated as well as post surgical patients.[11]

DISEASE PROGRESSION AND TREATMENT CONSIDERATIONS

The course and prognosis of the different glomerular diseases are extremely variable and depend on the underlying etiology. In glomerular diseases with a secondary cause, such as poststreptococcal glomerulonephritis, after the initiating factor is removed, the prognosis of the renal disease is often good. In contrast, the rates of renal function deterioration among the primary glomerulonephritides vary according to the form of glomerulonephritis. The majority of patients with minimal-change disease, IgA nephropathy, and membranous nephropathy have a fairly good prognosis. However, those with focal segmental glomerulosclerosis who are resistant to therapy, as well as those with rapidly progressive glomerulonephritis who are untreated, are likely to experience rapid loss of renal function. In some instances, half of the renal function may be lost within a 3-month period. Certain glomerulonephritides, such as minimal-change nephropathy, are very responsive to treatment. In contrast, for some other types of glomerulonephritis, such as membranous proliferative glomerulonephritis, consistently effective therapy has yet to be found.

Because of the variable courses exhibited by the different glomerulonephritides, specific treatment approaches have been developed for each disease. The natural history of the glomerulonephritis has to be well delineated before a promising regimen can be evaluated, from both therapeutic and economic perspectives. Otherwise, patients will be exposed to unnecessary treatment-related toxicities if they have a type of glomerulonephritis that is likely to undergo spontaneous remission. The potential therapeutic benefits of treatment regimens should always be weighed against the risks to which the patients are being exposed. It is therefore imperative to identify patients who are most likely to benefit from treatment, especially those who have other risk factors that may contribute to the deterioration of their renal function. In those instances in which satisfactory regimens are not available to treat the primary disease, appropriate supportive measures should be employed. Optimization of systemic and glomerular pressure, reducing proteinuria, and possibly controlling hyperlipidemia may all improve the long-term outcome as well as the quality of life of these patients.

Evaluation of Therapeutic Outcomes

4 Patients should be monitored closely for therapeutic response as well as the development of treatment-related toxicities. Although the rate of renal function deterioration is an important indicator of the long-term success of treatment, resolution of nephrotic and nephritic signs and symptoms associated with the glomerulopathies is an important short-term therapeutic target.

Serum creatinine concentration as well as creatinine clearance should be evaluated prior to and during treatment; 24-hour urine outflow should be collected to determine the extent of proteinuria. Alternatively, the daily urine protein excretion may be estimated from the urinary total protein-to-creatinine concentration ratio. After establishing the correlation between the 24-hour urinary protein excretion and the protein-to-creatinine ratio, single, random urine specimens may be used in place of a 24-hour urine collection. Blood pressure should be monitored periodically to assess the need for and the adequacy of antihypertensive therapy. The pressures should also be evaluated in conjunction with clinical signs and symptoms of edema and fluid overload to gauge the need for volume control as well as diuretic use. For patients with nephrotic syndrome, serum lipid concentrations should be monitored. If the patient has hematuria, urinalysis and a complete blood count should be obtained. The clinician should also be aware of the patient's appetite and energy level, because these are indicators of the patient's overall state of well-being. At times, renal biopsy is needed to assess response to treatment and disease progression, to determine future treatment strategy, and to confirm the initial diagnosis.

Patients receiving cytotoxic drug treatment should be evaluated for drug-related toxicities every week during the initial treatment period. After 1 month of treatment, the frequency of monitoring may be reduced. When the patient is on long-term steroid treatment, monthly visits are often required for assessment of both efficacy and toxicities. If a favorable response is obtained after a course of treatment, the patient may be evaluated every 3 to 4 months. The patient's renal function, proteinuria, urinalysis, blood pressure, lipid profile, and the overall state of health should be assessed during these regular follow-up visits.

INDIVIDUAL GLOMERULOPATHIES

MINIMAL-CHANGE NEPHROPATHY

Epidemiology and Etiology

Minimal-change nephropathy (also termed nil disease or minimal-change disease) is commonly found in children, accounting for about 85% to 90% of all cases of nephrotic syndrome in children between 1 and 4 years of age. The percentage drops gradually to less than 50% after age 10 years and accounts for less than 20% of all cases of idiopathic nephrotic syndrome in adults. Secondary causes of minimal-change nephropathy include NSAIDs, lupus, and various T-cell–related disorders, such as Hodgkin disease and leukemias.

Pathophysiology

Minimal-change disease is characterized by the absence of definitive pathologic changes observed under light and immunofluorescence microscopy. The characteristic lesion in patients with minimal-change disease, as visualized under electron microscopy, is the spreading and fusion of the foot processes of epithelial cells over an unchanged GBM. Lipoid nephrosis is another term that has been used to describe this type of glomerular disease because lipids, as well as renal tubular cells, are found in the urine. The pathogenesis of minimal-change disease is unknown. Altered cell-mediated immunologic response, specifically T-cell dysfunction or changes in the T-cell subpopulations, may be responsible. The activated lymphocytes are thought to secrete lymphokines that reduce the production of anions in the GBM. The permeability of the GBM to plasma albumin is increased through a reduction of electrostatic repulsion. The loss of anionic charges also results in fusion of the epithelial cell foot processes. Other vascular permeability factors, such as hemopexin, IL-4, and vascular endothelial growth factor, also have been suggested to be responsible.

Clinical Presentation

Most patients present initially with edema, frequently acute in onset, following a nonspecific upper respiratory tract infection, allergic reaction, or vaccinations, which might have activated the T lymphocytes. Nephrotic syndrome with massive proteinuria (substantially more than 40 mg/m^2 per hour for children and greater than 3-3.5 g/day for adults), edema, hypoalbuminemia, and hyperlipidemia is common. The patient's weight may increase dramatically because of sodium and fluid retention. Nephritic features, such as gross hematuria, are uncommon. Hypertension and decreased renal function are uncommon in children but are more common in older adults.[32] For some patients, volume depletion may result in mild to moderate azotemia.

TREATMENT

Minimal-Change Nephropathy

PHARMACOLOGIC THERAPY

Steroids

Initial Therapy 5 Minimal-change disease is most responsive to initial treatment with corticosteroids. In children, steroid therapy is expected to reduce proteinuria in approximately 90% of the patients, with >95% 10-year renal survival.[33] Because of the excellent response to initial therapy with steroids and the prevalence of this glomerular disease in children, reduction of proteinuria secondary to steroid treatment is considered diagnostic for minimal-change disease without the need for biopsy. Prednisone is commonly administered at 60 mg/m^2 per day initially for 4 to 6 weeks. The dose is then reduced to 40 mg/m^2 per day every other day for another 4 to 6 weeks, with or without tapering afterward (Fig. 56–3).[34] Proteinuria will disappear in 50% of patients after 1 week and in 90% of patients after 4 weeks of treatment. Different versions of the steroid regimen are available as there is no consensus on the optimal dose and duration. Studies are being conducted to identify the best strategy to induce remission, reduce disease recurrence, and minimize adverse effects of the therapy. Commonly, the initial episode is treated with an extended course (months) of therapy, followed by shorter treatment (weeks) for relapses.[35]

For adults, prednisone 1 mg/kg per day is given initially for 4 weeks with a reduction to 0.75 mg/kg every other day for the next 4 weeks. Proteinuria will disappear in 50% to 60% of patients after 8 weeks of treatment, and complete remission will be attained in 80% of patients after 28 weeks of therapy.[32]

Relapse As many as 85% of the patients who respond to initial steroid therapy (steroid sensitive) will experience a relapse of proteinuria, mostly within 6 to 12 months after disease onset. The risk of relapse is affected by the duration of initial steroid therapy.[11,34] Children who were asymptomatic with proteinuria diagnosed during routine urine screening tend to have less-frequent relapses and a more favorable clinical course. In those who relapse, 50% to 65% may have steroid-responsive relapse episodes over the subsequent 3- to 5-year period. The dose and duration of steroid treatment for the relapse do not influence the subsequent rate of relapse.[11,34] Commonly, 60 mg/m^2 per day of prednisone is given until the urine is free of protein for 3 days, to be followed by 4 weeks of alternate-day prednisone at 40 mg/m^2 per dose.[34]

Frequent Relapse Approximately 10% to 20% of children will experience three or four relapses that are responsive to steroid. Half of them will then relapse frequently and become steroid dependent, requiring continuous low-dose alternate-day prednisone to maintain an extended relapse-free period.[34] A small number of patients eventually develop resistance to steroids, and a biopsy done at that time often reveals another pathology such as focal segmental glomerulosclerosis. It is controversial whether minimal-change disease progresses into focal segmental glomerulosclerosis or whether the glomerulosclerosis that was present at the time of initial diagnosis was inadvertently diagnosed as minimal-change nephropathy because of tissue-sampling error during the renal biopsy.

Cytotoxic Agents

Cytotoxic agents are often considered for patients who are steroid resistant, as well as for those who require large doses of steroids to sustain remission (steroid dependent). These agents are also beneficial for pediatric patients who experience growth inhibition secondary to chronic use of steroid.[11] Cytotoxic agents are effective in inducing remission and the duration of remission tends to be longer than that induced by steroid. In those patients who relapse after cytotoxic therapy, they may respond to steroid better than before.

Cyclophosphamide at 2 mg/kg per day for 10 to 12 weeks given alone or with prednisone (50 to 75 mg/m^2) is very effective in inducing remission and restoring steroid responsiveness for patients who

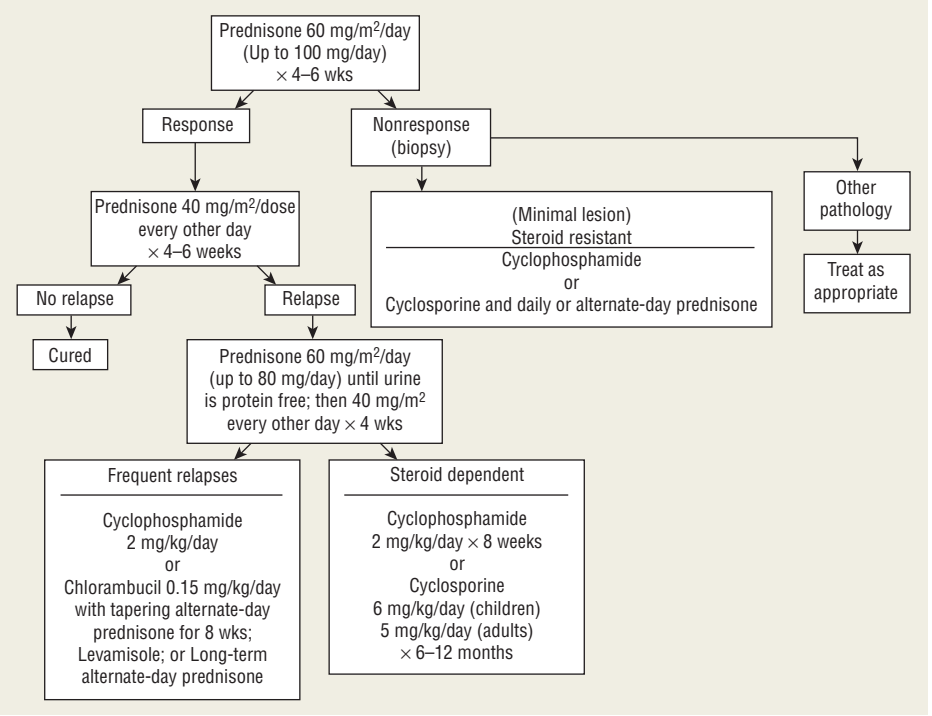

FIGURE 56-3. Treatment algorithm for minimal-change nephropathy. (*Reprinted by permission from Macmillan Publishers Ltd: Bargman JM. Management of minimal lesion glomerulonephritis: Evidence-based recommendations. Kidney Int Suppl 1999;55:S3–S16.*)

were previously steroid dependent and then became steroid resistant. Alternatively, chlorambucil at 0.1 to 0.2 mg/kg per day may be used. This agent, however, is associated with more adverse effects than cyclophosphamide. Azathioprine has also been used; however, treatment for 6 to 12 months is often needed before any favorable response is apparent.

The immunosuppressive effect of cytotoxic agents, with or without the concurrent use of steroids, can result in serious infections, which are the primary cause of death for patients with minimal-change nephropathy. Other toxicities associated with cyclophosphamide include gonadal fibrosis, which results in sterility, hemorrhagic cystitis, alopecia, and a potential to develop malignancy in those on long-term treatment.

Cyclosporine

Cyclosporine decreases lymphokine production by activated T lymphocytes and thereby reduces proteinuria by reversing the lymphokine-induced alterations in the anionic charge and permeability of the GBM to albumin. For patients with steroid-sensitive or steroid-dependent disease, cyclosporine induces remission in 80% to 85% of patients. However, the disease-free period is not often sustained, and relapse, which is usually not as responsive to cyclosporine retreatment, may occur as soon as the drug is tapered or discontinued. The steroid-sparing effect of cyclosporine is also useful for steroid-dependent patients, especially those who have experienced significant adverse effects.

The usual starting dose of cyclosporine for remission induction is 5 mg/kg per day for adults and 100 to 150 mg/m^2 per day for children. Similar dosages are used to maintain remission long term. The optimal cyclosporine blood concentrations, as well as the need to monitor them, are controversial. No correlation has been found between the severity of the cyclosporine-induced tubulointerstitial lesions and the mean dose or trough drug concentration. However, monitoring of the area under the serum concentration–time curve has been suggested and target exposures have been proposed.[36] Testing the in vitro sensitivity of peripheral blood lymphocytes to cyclosporine in the presence of a T-cell mitogen may offer a novel method to predict response and individualize therapy.[37]

Adverse events such as rise in serum creatinine, hypertrichosis, and gingival hyperplasia are quite common. Long-term therapy may result in persistent hypertension and progressive renal failure. Cyclosporine should not therefore be given for more than 4 months in the absence of any beneficial effect. Consequently, it is indicated for patients (1) who relapse frequently or are steroid dependent, after failing to respond to a course of cyclophosphamide; (2) for whom cyclophosphamide is contraindicated or when gonadal toxicity is a concern; (3) who are steroid dependent when a "steroid holiday" is needed for catch-up growth and puberty; or (4) who have steroid-resistant disease.[34]

Levamisole

Levamisole, an immunostimulant, can promote the maturation of young T cells and restore the function of T cells and phagocytes when the immune system is depressed. It may also inhibit the production of an immunosuppressive lymphokine. Levamisole was found to have a steroid-sparing effect and was capable of maintaining remission in children who had frequent relapse steroid-dependent nephrotic syndrome.[38] In addition, it is as effective as cyclophosphamide in reducing relapse rate and steroid dosages.[39] The most serious adverse effect of levamisole is neutropenia, which is generally reversible. At present the drug is no longer available in the United States; however, it is still used elsewhere in the world for select steroid-dependent patients.

Mycophenolate Mofetil

Mycophenolate mofetil is an immunosuppressant that can suppress T- and B-cell lymphocyte proliferation, B-lymphocyte antibody production, and expression of adhesion molecules. It is reported to have steroid-sparing effects and to be useful in steroid-dependent patients, as well as in those who fail cytotoxic thereapy.[40,41]

Therapeutic Outcomes

The long-term prognosis of most patients with minimal-change disease is good. The majority of pediatric patients will not experience any relapse of the disease 10 years after the initial onset, and most will be free of the proteinuria after puberty. In adults, an 85% to 90% survival rate is seen 10 years after disease onset. Although this condition may spontaneously remit in up to 70% of untreated adults, life-threatening complications may be associated with untreated nephrotic syndrome. Significant deterioration in renal function is uncommon in both adult and pediatric patients and is observed only in those who are steroid resistant or steroid dependent. Because of the overall favorable outcome of the disease and the relatively uncommon progression into chronic renal failure, aggressive use of cytotoxic agents is not indicated even for most patients with frequent relapses. Toxicities associated with aggressive therapy do not justify the need to induce remission in those patients who fail to respond to steroids and the nonaggressive use of cytotoxic agents. Symptomatic therapy with diuretics to control edema, in conjunction with a low-salt diet and albumin infusion as needed for acute development of anasarca, is often a more rewarding therapeutic approach. NSAIDs and ACEIs may also be used to reduce the proteinuria.

FOCAL SEGMENTAL GLOMERULOSCLEROSIS

Etiology and Epidemiology

Focal segmental glomerulosclerosis (FSGS) is a clinicopathologic condition that can be idiopathic (primary) or secondary to a variety of causes. FSGS accounts for less than 15% of the cases of idiopathic nephrotic syndrome in children and approximately 15% to 20% in adults; however, it may account for 36% to 80% of the cases in African Americans.[42] The incidence of FSGS has been rapidly increasing, so that it now is the most common glomerular disease that ultimately leads to ESRD. Conditions such as sickle cell disease, cyanotic congenital heart disease, and morbid obesity can induce hemodynamic stress on an initially normal nephron population and result in FSGS. Severe glomerular injury can also be seen in patients with nephropathy associated with heroin abuse, human immunodeficiency virus (HIV) infection, and genetic mutations involving the podocin and WT1 genes.[42] A recent case series identified the association of FSGS and proteinuria in bodybuilders after long-term anabolic steroid abuse.[43] The primary and secondary sclerotic lesions may be morphologically similar, but they represent diseases with different courses and responses to therapy.

Pathophysiology

Sclerotic lesions are characteristically found in some of the glomeruli (focal) and usually involve only a portion of the glomeruli (segmental).[44] Similar to minimal-change disease, fusion of foot processes is commonly seen in those glomeruli that are not sclerotic. It is thought that both minimal-change disease and FSGS share similar pathogenetic mechanisms, with FSGS resulting in severe injury to the glomerular epithelial cells. During the early stage of FSGS, only a small number of glomeruli may have the segmental sclerotic lesion, and the disease may be confined to the

juxtamedullary region. If an inadequate number of glomeruli are sampled during renal biopsy, the diagnosis of FSGS may be missed, or the patient may be thought to have minimal-change disease. Resistance to steroid therapy may thus be one of the first clues that the patient, indeed, has FSGS rather than minimal-change disease. Alternatively, a patient may have the steroid-sensitive minimal-change disease initially, which subsequently progresses to steroid-resistant FSGS.

Clinical Presentation

Almost all the patients present with proteinuria, and many of them have all the features of nephrotic syndrome. The proteinuria is nonselective, containing albumin and other higher-molecular-weight proteins, and is usually less severe when compared to patients who have minimal-change disease. Hypertension, microscopic hematuria, and renal dysfunction may be seen in up to half of the patients. Reduced renal function becomes more prevalent as the disease progresses.

The presenting clinical features in nephrotic adults with minimal-change nephropathy can be indistinguishable from that of FSGS, and renal biopsy is therefore critical in the diagnosis of adults with nephrotic syndrome. African Americans have a fourfold higher risk of developing FSGS than white or Asian patients. They tend to develop the disease earlier and present with nephrotic range proteinuria more often. They are less responsive to steroids and are more likely to experience a rapid decline in renal function, resulting in ESRD.

TREATMENT

Focal Segmental Glomerulosclerosis

PHARMACOLOGIC THERAPY

Steroids

6 The treatment of FSGS is controversial because of the lack of data from randomized, prospective, controlled trials. A course of prednisone (1 to 2 mg/kg per day) with tapering after 3 to 4 months of treatment is first used for nephrotic patients.[42,44] Urinary protein excretion and serum albumin concentration should be monitored to assess efficacy. The median time to induce complete remission is 3 to 4 months, although 5 to 9 months may be needed in some patients.[42] In general, 30% to 40% of all patients can be expected to attain complete remission; for those who are not responding, treatment should be continued for 6 months before they are considered steroid resistant.[45]

If the patient develops a relapse after an adequate response to the initial treatment, a second course of steroids is generally sufficient.[42] However, if relapse occurs frequently, cytotoxic agents or cyclosporine would be indicated.

For patients who are not nephrotic, their relatively favorable prognosis does not support using steroids or other immunosuppressive agents. However, close follow-up and good blood pressure control with ACEIs are necessary to minimize disease progression.[44]

Most of the studies conducted thus far include mostly white patients. In a recent retrospective review of 72 patients that included 65 African-American patients, steroid use was not associated with renal survival or the induction of proteinuria remission.[46] The initial creatinine level, blood pressure, and severity of renal lesion are significant factors for renal survival. About one third of the patients who received steroids developed complications such as diabetes and significant weight gain.

Cytotoxic Agents

When used with steroids during initial therapy, cytotoxic agents were not found to offer any additional beneficial effect.[42] For those patients who are not responding to steroids during initial therapy, cytotoxic agents such as cyclophosphamide (2 mg/kg/day) and chlorambucil (0.1 to 0.2 mg/kg/day) have been used with pulse methylprednisolone to induce remission. Response rates as high as 66% have been reported in uncontrolled trials, although such favorable responses have not been universally observed.[42]

Calcineurin and Rapamycin Inhibitors

In steroid-resistant patients, cyclosporine therapy has produced a complete or partial remission in 70% of patients, with a relapse rate of 47%.[47] Encouraging results have also been reported with the concurrent use of cyclosporine and steroid.[42] Adverse effects of cyclosporine commonly include gingival hyperplasia, hypertrichosis, hypertension, and renal insufficiency. In an attempt to minimize the long-term side effects, a regimen that included periodic cyclosporine dose reduction when given with steroid, cyclophosphamide, and mycophenolate mofetil was developed, and favorable effects were observed.[48] Tacrolimus has also been used to induce remission and reduce proteinuria for patients with refractory disease.[49] The effect of sirolimus on proteinuria has been found to be conflicting, however, it may cause a rapid decline in GFR, and hence, its use for FSGS in not recommended.[50]

Mycophenolate Mofetil

Mycophenolate mofetil has been reported to have favorable effects for patients who were steroid resistant, many of whom had failed to respond to other cytotoxic agents and cyclosporine.[51] Forty-four percent of the patients had reduced proteinuria and the improvement was sustained in 50% for up to 1 year. Deterioration of renal function was not observed. Other investigators have reported similar experiences. Further studies are needed to define the role of this agent among the various treatment options.

Symptomatic Therapy

Because of the lack of a consistently effective regimen for primary FSGS, many patients with mild disease are treated conservatively. ACEIs and ARBs are effective in reducing proteinuria and in stabilizing renal function in many patients with primary or secondary FSGS.[42] For patients who have nephrotic range proteinuria, an elevated serum creatinine concentration and interstitial scarring on biopsy, corticosteroids with or without immunosuppressive agents are often used.

THERAPEUTIC OUTCOMES

ESRD develops within 10 years in 10% or less of the 30% to 50% of adults and children who had attained complete remission.[47] For those patients who are resistant to therapy, the rate of renal function deterioration to ESRD may be rapid, within 1 year, or slow, over as long as 10 to 20 years; approximately 50% develop ESRD within 10 years. Those patients with severe proteinuria (>10 to 15 g/day), high serum creatinine concentration at diagnosis, initial steroid resistance, or interstitial fibrosis on renal biopsy are likely to have a more rapid decline in renal function.[44] African-American patients may also have a higher risk. Kidney transplantation is often indicated for those patients who develop ESRD; however, FSGS has recurred in 20% to 50% of the renal

allografts soon after transplantation. Children and those with severe disease or rapid progression to ESRD prior to transplantation are more likely to experience a recurrence. The proteinuria may reappear within hours after transplantation, and graft failure may occur in one third to one half of the patients. The median time to recurrence was reported to be 14 days in one study. Although cyclosporine is ineffective in preventing the recurrence of nephrotic syndrome after transplantation, a high dose of the agent (up to 35 mg/kg per day) induces a remission of the recurrent disease. ACEIs and plasmapheresis are also used to prolong graft survival. The effectiveness of these therapies and the rapid recurrence of the disease in the transplanted kidney substantiate the possibility that a circulating humoral mediator is responsible for the nephropathy.

MEMBRANOUS NEPHROPATHY

Etiology and Epidemiology

Membranous nephropathy is the most common disorder responsible for idiopathic nephrotic syndrome in adults, accounting for about 20% to 25% of cases. It is also a frequent cause of renal failure secondary to glomerulonephritis. The hallmark histologic features of membranous nephropathy are glomerular capillary wall thickening with subepithelial deposits under light and electron microscopy. Most cases are idiopathic, but approximately 25% of adults and 80% of children have secondary causes.[52,53] In the United States, the most common etiologies are autoimmune diseases (e.g., lupus), infection (e.g., hepatitis B and C), syphilis, neoplasm (e.g., carcinoma of the lung, breast, gastrointestinal tract, or kidney), and medications (e.g., gold, penicillamine, or captopril). Malaria and schistosomiasis are common causes in other parts of the world. De novo membranous nephropathy can also occur in the allografts of renal transplant patients. Because the responses to therapy as well as the prognosis for idiopathic and secondary membranous nephropathy are different, it is important to identify any potential underlying causes for the nephropathy prior to treatment. Although this glomerular disease can occur at any age, the peak incidence is between ages 30 and 50 years and is especially likely in patients older than age 50 years who present with nephrotic syndrome.[52]

Pathophysiology

Examination of kidney tissue under light microscopy reveals normal mesangium and normocellularity. The glomerular capillary wall may be thickened in well-developed lesions. In the advanced stage, the capillary wall is markedly thickened, and intramembranous deposits are found. Progressive changes in capillary lumen patency parallel those in the GBM, resulting in glomerulosclerosis with capillary collapse and tubular atrophy in end-stage membranous nephropathy. Immunofluorescence microscopy shows strong capillary wall staining of IgG and C3 on the epithelial side of the basement membrane. Antibody-mediated immune injury appears to be the main pathogenetic mechanism. The immune complex can be formed in situ or deposited from circulating immune complexes.

Clinical Presentation

Most patients with membranous nephropathy present with heavy proteinuria (exceeding 3.5 g/day). Those patients excreting large amounts of IgG and α_1-microglobulin, indicating more significant tubulointerstitial damage, have a lower remission rate and are more likely to progress toward renal failure.[52]

The signs and symptoms are usually insidious in onset and may consist of anorexia, malaise, edema, anasarca, or ascites, and pericardial and pleural effusions may also be present. As a result of a hypercoagulable state, pulmonary embolism may develop but rarely results in death. The incidence of renal vein thrombosis varies from 5% to 62%,[53] and membranous nephropathy should be suspected when there is a sudden onset of hematuria, loin pain, pulmonary embolus, fluctuating or worsening proteinuria or GFR, renal tubular acidosis, or an increase in leg edema. Hypertension is found in approximately 30% of patients and is more common with renal insufficiency or in advanced disease.

In addition to heavy proteinuria, urinalysis often reveals lipiduria and oval fat bodies. Microhematuria is seen in fewer than 25% of patients, and gross hematuria and red cell casts are rare. In idiopathic membranous nephropathy, the serum complement concentrations are normal. Low levels of complement should alert one to search for secondary causes, such as lupus, hepatitis B infection, or an alternative diagnosis. Similarly, antinuclear antibodies, anti-DNA antibodies, rheumatoid factor, hepatitis B serologies, and serum cryoglobulins are generally negative in idiopathic membranous nephropathy. Occult malignancy has been found in as many as 10% of elderly patients with membranous nephropathy.

The natural course of idiopathic membranous nephropathy is variable. Up to 30% of the patients experience spontaneous remission, commonly within 2 years of disease onset. Half of the remaining patients have persistent proteinuria with long-term preservation of renal function, while the other half has gradual loss of renal function.[52] Heavy proteinuria (>10 g/day), male gender, elevated serum creatinine concentration at the time of presentation; poorly controlled hypertension, advanced age at onset of disease, non-Asian race, certain human leukocyte antigen phenotypes, and tubulointerstitial fibrosis on initial renal biopsy are associated with progressive renal disease.[52,53] A predictive algorithm, incorporating the level of proteinuria, initial creatinine clearance, as well as the slope of renal function decline over 6 months, has been developed to determine the risk for disease progression.[52]

In general, patients with idiopathic membranous nephropathy have a relatively benign course with mean 10-year survival of approximately 70%. Those who present with persistent nonnephrotic proteinuria seldom develop renal insufficiency and have a normal life expectancy. Fewer than 10% of patients develop a remitting and relapsing course.[53] The prognosis for secondary membranous nephropathy depends on the underlying cause. Remission occurs when the infection resolves or when the causative medication is withdrawn.

TREATMENT

Membranous Nephropathy

The treatment of idiopathic membranous nephropathy is controversial and ranges from supportive therapy to immunosuppression. Conservative management of patients with mild disease includes edema control with salt restriction and diuretics[5] and reduction of proteinuria with protein restriction and ACEIs (Fig. 56–4).[53] Management of hypertension and hyperlipidemia is required for most patients, whereas prophylactic anticoagulation, despite having benefits shown to outweigh the risks, is usually given only for patients with renal vein thrombosis or documented pulmonary embolus.[31,53]

PHARMACOLOGIC THERAPY

Steroids

Remission of proteinuria, whether spontaneously or treatment related, may confer a good prognosis. Corticosteroids alone were

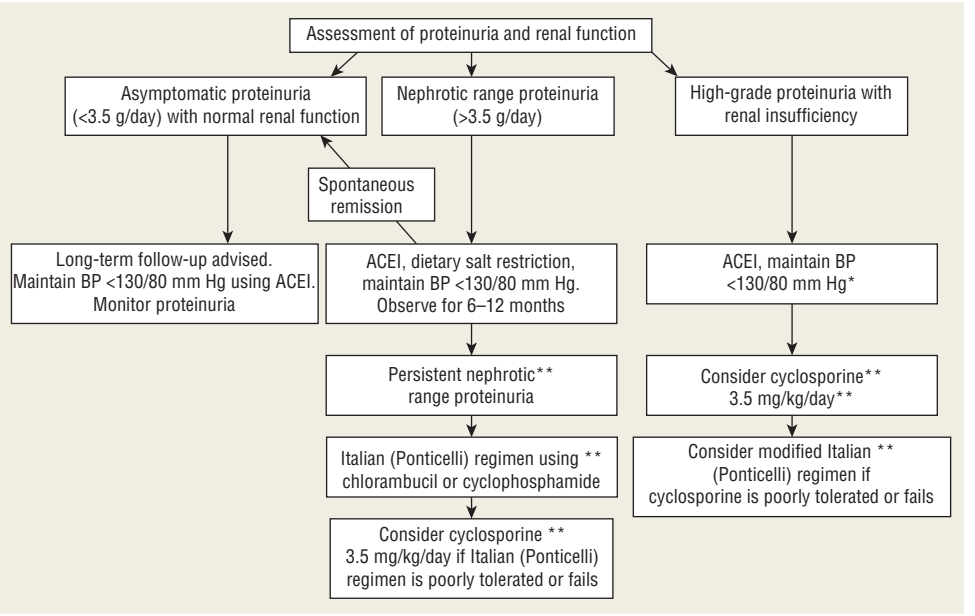

FIGURE 56-4. Treatment algorithm for idiopathic membranous nephropathy. Patients may change from one category to another during the course of follow-up. (*, supported by evidence from controlled trials; **, introduction of risk reduction strategies for both secondary effects of disease and adverse effects of immunotherapy; ACEI, angiotensin-converting enzyme inhibitor; BP, blood pressure.) (*This article was published in Semin Nephrol, 20, Geddes CC, Cattran DC, The treatment of idiopathic membranous nephropathy, 299–308, Copyright © Elsevier 2000.*)

ineffective in improving proteinuria remission rate in all controlled trials and in preventing progression in all but one study.[51] The result of a metaanalysis also confirmed the lack of efficacy of steroids when used alone.

Cytotoxic Agents

Cytotoxic agents, when used in conjunction with corticosteroids, are effective in increasing the remission rate of proteinuria and preserving renal function. Ponticelli and colleagues devised such a regimen by combining intravenous methylprednisolone (1 g) for 3 days followed by oral methylprednisolone (0.4 mg/kg) for the subsequent 27 days of months 1, 3, and 5. Oral chlorambucil (0.2 mg/kg) is to be given daily in months 2, 4, and 6.[54] The 10-year renal survival was increased to 92% when compared with 60% in the control group. They later substituted cyclophosphamide (2.5 mg/kg per day) for chlorambucil, which resulted in similar rates of proteinuria remission and relapse, but with fewer serious side effects in those who received cyclophosphamide.[55]

Results from a recent metaanalysis of randomized, controlled trials affirmed that cytotoxic agents, but not steroids, are effective in reducing nephrotic-range proteinuria, with cyclophosphamide having fewer adverse effects than chlorambucil.[56]

Cyclosporine

A controlled trial found that cyclosporine, given at a dose of 3 to 4 mg/kg/day for 6 months, was effective for patients with medium risk for disease progression.[52] For patients with severe nephrotic syndrome and deteriorating renal function who do not respond to cytotoxic therapy, cyclosporine may offer some benefits; however, the risk for cyclosporine nephrotoxicity is of concern, especially during long-term therapy. A 12-month course of cyclosporine (mean dose: 3.8 mg/kg/day) was found to reduce proteinuria as well as the rate of renal deterioration.[57] In a recent study of 41 patients who received cyclosporine, many with concurrent steroid and ACEI therapy, the median treatment time to complete remission was 225 days among the 34% of patients who attained complete remission.[58] During such long-term treatment, hypertension may be exacerbated and the serum creatinine concentration may be increased because of nephrotoxicity. When the renal function declines, the dose of cyclosporine should be reduced.

Alternative Therapeutic Options

Because spontaneous remission is common and only approximately 25% of patients with new-onset idiopathic membranous nephropathy ultimately develop ESRD in 20 to 30 years, it is prudent not to aggressively treat all patients at the onset of the disease. Patients who have a low risk for renal disease progression can be managed with observation and symptomatic therapy. Normalizing the blood pressure and reducing proteinuria with ACEIs and/or ARBs are important as both hypertension and proteinuria are independent risk factors for the progression of renal failure.[52] Patients with low risk for renal disease progression include children 2 to 16 years of age, adult males with proteinuria less than 2 g/day, or adult females with proteinuria less than 5 g/day and normal renal function. In contrast, patients who have a high risk of developing renal failure, including those with proteinuria greater than 10 g/day with or without impaired renal function, and patients with symptomatic nephrotic syndrome with a plasma albumin of less than 2 g/dL (20 g/L) should be aggressively treated to induce remission. An alkylating agent such as cyclophosphamide or chlorambucil, combined with steroids, should be given to induce remission. Recently, rituximab was shown to be effective in treating small number of patients, while eculizumab was not effective.[59–61] Mycophenolate mofetil was not more effective or better tolerated than cyclophosphamide.[62] Tetracosactide, a synthetic analog of adrenocorticotropic hormone, has also been shown in small studies to offer results superior to the cytotoxic–steroid combination regimen.[63]

The cytotoxic–steroid combination regimen may be effective in inducing remission in the 30% to 40% of the medium-risk patients who relapse within 2 years after treatment discontinuation. Alternately, cyclosporine may be used with similar effectiveness.[52] The cyclophosphamide–steroid combination should also be used for relapse in high-risk patients.

For patients with a transplanted kidney, both de novo and recurrent membranous nephropathy may occur. Patients with primary membranous nephropathy are more at risk. Recurrence is typically associated with nephrotic syndrome and a high risk of allograft failure from disease and/or rejection.

MEMBRANOPROLIFERATIVE GLOMERULONEPHRITIS

Etiology, Epidemiology, and Pathophysiology

Membranoproliferative glomerulonephritis (MPGN) is one of the least-common renal morphologic entities that occur in older children and adults. For some unclear reason, the incidence of MPGN has been decreasing over the past few decades in the United States and Europe. However, in Africa and Asia, idiopathic MPGN is still common, perhaps secondary to exposure to unrecognized infectious and parasitic agents.

The several types of MPGN are classified according to the pathologic features. Type I MPGN, also known as mesangiocapillary glomerulonephritis, is characterized by diffuse thickening of glomerular capillary walls and mesangial hypercellularity. Immune complexes are presumed to have a major role in the pathogenesis of type I MPGN, which is the most common type of primary, idiopathic MPGN.

Type II MPGN is also known as dense-deposit disease (DDD) because of the presence of dense deposits of C3 within the GBM, which gives rise to a ribbon-like appearance. Other variants of the disease include type III MPGN, which is seen rarely and consists of subendothelial and subepithelial deposits with lamination and disruption of the lamina densa of the GBM.

Type I MPGN is a slowly progressive disease that accounts for 80% of all MPGN, but only 5% to 15% of all cases of nephrotic syndrome seen in pediatric and adult patients. It occurs most frequently for patients between 5 and 30 years of age, and because remissions are rare, many patients eventually develop ESRD. The renal survival is 60% to 65% at 10 years, and the presence of nephrotic syndrome, interstitial disease, and hypertension are poor prognostic indicators.[64] Type II MPGN is a more aggressive disease that constitutes approximately 15% of all patients with MPGN. Only 20% of patients remain stable for more than a few years, and the median time before the development of ESRD is 7 years.

Clinical Presentation

Nephrotic syndrome is the most common presenting condition although some patients may also have a nephritic component (hematuria), hypertension, and renal insufficiency. Hypocomplementemia is commonly seen.

TREATMENT

Membranoproliferative Glomerulonephritis

STEROIDS

The efficacy of corticosteroids, cyclophosphamide, antiplatelet drugs, and anticoagulants has been evaluated for the treatment of MPGN. In children, prednisone 40 mg/m^2 given on alternate days is effective, when compared with placebo, in reducing the decline in GFR.[65] This observation was confirmed by other uncontrolled studies.[64] Consequently, prednisone should be given for 6 to 12 months to children with MPGN, proteinuria (more than 3 g/day), and/or impaired renal function.[64] Other studies suggest that this regimen may also be beneficial in children with mild proteinuria.

Although the effect of steroids has not been proven in adults, antiplatelet drugs, such as dipyridamole and aspirin, as well as warfarin, were found in randomized controlled trials to reduce proteinuria but had no effect on GFR.[64] Subcutaneous heparin has also been used in a small number of patients with favorable results.[66] Adult patients with idiopathic MPGN, heavy proteinuria, and/or impaired renal function should be given dipyridamole or aspirin. Unfortunately, no controlled study comparing the effect of steroids with antiplatelet agents is yet available.

CYTOTOXIC AGENTS

Cyclophosphamide and azathioprine were found to have no beneficial effect. Cyclosporine was evaluated in a limited number of patients with MPGN with some beneficial effect; however, the trials were not controlled or randomized. In addition, the risks for developing adverse effects were high. Figure 56–5 presents an algorithm for treatment and follow-up of MPGN.

ANTIPLATELET AGENTS

Although several studies have shown dipyridamole and aspirin to reduce proteinuria, reduction of GFR decline was not generally observed.[64] Consequently, antiplatelet therapy should be considered

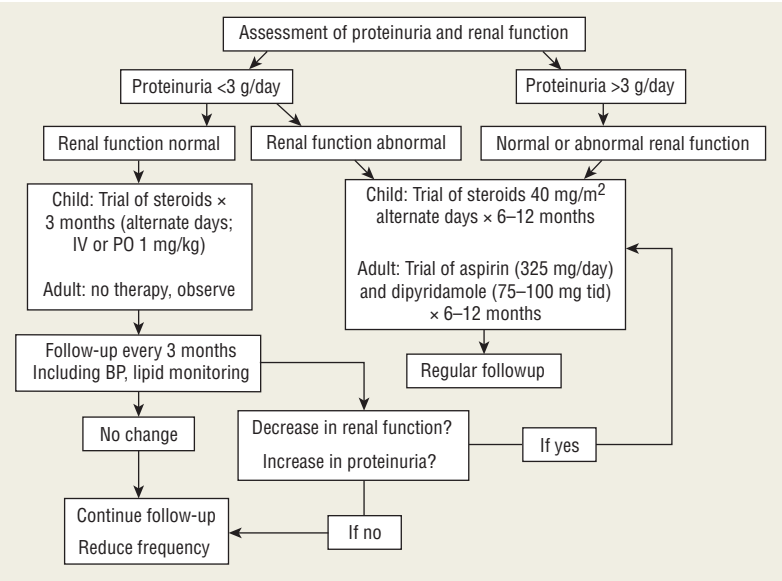

FIGURE 56-5. Treatment algorithm for membranoproliferative glomerulonephritis. (BP, blood pressure.) (*Reprinted by permission from Macmillan Publishers Ltd: Levin A. Management of membranoproliferative glomerulonephritis: Evidence-based recommendations. Kidney Int Suppl 1999;55:S41–S46.*)

as a viable option only for those patients with significant proteinuria. There should be periodic follow up of patients to assess proteinuria and renal function.

Since steroids are not known to be effective for type II disease other yet-to-be-proven strategies such as rituximab, eculizumab, sulodexide, and plasma infusion or exchange may be considered.[67] It is difficult to conduct large-scale controlled trials for MPGN because of the low incidence of the disease. Based on the available studies, many of the drugs evaluated do not have any consistent, beneficial effect on renal function and proteinuria. Renal transplantation is an alternative; however, the recurrence rate is close to 100% for type II MPGN and is approximately 20% to 30% for type I MPGN. Half of the allografts ultimately fail.

IMMUNOGLOBULIN A NEPHROPATHY

Etiology and Epidemiology

IgA nephropathy, also known as *Berger disease*, was first described in France in 1968. It now is the most common primary glomerulonephritis in the world and accounts for 10% of patients with ESRD in many countries. The prevalence among patients with glomerulonephritis or patients who had kidney biopsy varies from as high as 50% in Japan and East Asia to 10% to 30% in Europe. In the United States, the overall prevalence is approximately 10% to 15% but is as high as 35% among Native Americans living in New Mexico.[68] These differences in prevalence may reflect variations in genetic predisposition, as well as the criteria used for urinary screening and kidney biopsy.

IgA nephropathy is more frequently seen in younger adults and is two to six times more common in males than in females. It is uncommon in blacks, both in the United States and in Africa.[68] IgA nephropathy was once thought to be a benign disease presenting with asymptomatic hematuria; however, its ability to present with any clinical syndrome associated with glomerular disease is now recognized. Some patients will develop ESRD over variable periods of time.

Pathophysiology

Primary IgA nephropathy is an immune-complex–mediated disease in which IgA deposits and other pathologic lesions are found in kidney tissues. In contrast, Henoch-Schönlein purpura, a systemic disease that is believed to be closely linked to IgA nephropathy, shares similar immunohistologic findings in the kidneys. Both typically have vasculitis affecting the joints, skin, and gastrointestinal tract, which may result from the same pathologic process of IgA nephropathy. The diagnosis of IgA nephropathy is established by the presence of mesangial IgA deposits upon immunofluorescence examination of the kidney biopsy. The IgA immune complex, composed of IgA antibody bound with an environmental antigen, such as a virus, bacteria, or food substances, is presumed deposited from the systemic circulation. Alternately, the complex may be formed in situ, with the IgA antibody bound with an endogenous antigen in the mesangium. In the mesangium, IgA can bind with receptors on the mesangial cells to induce proliferation and cytokine production. In addition, IgA can activate complement through the alternate pathway to induce glomerular damage.[69] The extent of the injury depends on the characteristics of the IgA that favor mesangial deposition, the susceptibility of the mesangium toward deposition, the ability of the patient to mount an inflammatory response to the deposits, and the response of the kidney to the injury in a way that favors progressive renal damage.[70]

Clinical Presentation

IgA nephropathy commonly presents in the second and third decades of life, but it can occur at any age. Many patients have microscopic hematuria and proteinuria for years, persistently or intermittently, during the early stages of the disease. About half of the patients present with gross hematuria concurrent with an infection, commonly in the upper respiratory tract.[68] The hematuria may occur 1 to 2 days after the onset of infection symptoms, which is different from the 10- to 14-day delay seen after the pharyngitis in poststreptococcal glomerulonephritis. Proteinuria is common, and nephrotic range often indicates advanced disease. Hypertension and edema are infrequent but are common in poststreptococcal glomerulonephritis.

Renal dysfunction is uncommon at the initial presentation; however, approximately 10% to 20% of the patients develop ESRD within 10 years, and 30% develop it after 20 years.[71] Hypertension, severe proteinuria, renal function impairment, old age, and the severity of histologic lesions are all predictive factors for poor long-term outcome.[69–71]

TREATMENT

Immunoglobulin A Nephropathy

Spontaneous remission is seen in only 10% to 25% of children and 5% to 7.5% of adults. Unfortunately, no therapy is known to be consistently effective for the treatment of IgA nephropathy. Because of the slow progression of the disease to ESRD, it is very difficult to conduct trials to evaluate the long-term effectiveness of specific treatments. The lack of understanding of the pathogenetic mechanisms and the unavailability of appropriate animal models severely limit the development of rational treatment regimens.

NONPHARMACOLOGIC THERAPY: LOW-GLUTEN DIET AND TONSILLECTOMY

Restriction of dietary gluten is effective for patients with celiac disease but not for patients with no identifiable nephritogenic antigens.[72] Removal of the tonsils, which produce IgA_1 and may contribute to IgA nephropathy, may reduce proteinuria and hematuria. This is especially helpful for patients who developed recurrent macroscopic hematuria as provoked by bacterial tonsillitis. There are limited studies to show the long-term renoprotective effects of tonsillectomy; however, larger studies with longer follow-up are needed to affirm such beneficial effect.[70]

PHENYTOIN

Phenytoin was evaluated because of its ability to reduce the amount of polymeric IgA in the circulation.[72] Although it reduced serum IgA concentrations and frequency of macroscopic hematuria, the glomerular lesions deteriorated in some of the patients and the drug is not generally used nowadays.

CORTICOSTEROIDS

Corticosteroids with or without immunosuppressive agents have been used to treat IgA nephropathy for many years. A recent metaanalysis of available trials showed that steroid therapy is associated with reduction in proteinuria, risk for progression to ESRD, as well as the rate of renal function deterioration.[73] Low-dose, short-term (<3 months) steroid therapy is not expected to yield favorable results. In contrast, larger doses of steroids (IV methylprednisolone 1g/day for 3 days at months 1, 3, and 5 and oral prednisone 0.5 mg/kg every other day for 6 months) were able to reduce proteinuria and renal function deterioration.[74] However, the dose of

the steroids and the risk for toxicity might be considered high by many.[70] Patients with nephrotic range proteinuria and impaired renal function are likely candidates for steroid therapy; however, the responses to such treatment are not favorable.

CYTOTOXIC AGENTS

Several studies have evaluated the efficacy of azathioprine and cyclophosphamide. In some of the studies, cyclophosphamide was used in conjunction with dipyridamole, heparin and warfarin. It is difficult to assess which of these agents contributed to the limited favorable effects observed. In addition, in many of these studies, blood pressure control and ACE inhibition were not always optimal. At present, there is no clear evidence to support the use of these cytotoxic agents for IgA nephropathy, except perhaps for those patients with advanced rapidly progressive disease.[70]

CLINICAL CONTROVERSY

Is fish oil effective for IgA nephropathy?

FISH OIL

The third approach is to reduce glomerular inflammation and glomerulosclerosis induced by IgA deposits. Antiinflammatory agents, antiplatelet drugs, and anticoagulants have been tried without success to decrease the production or action of mediators responsible for IgA immune-complex–induced glomerular damage.

However, the *n*-3 fatty acids in fish oil reduce the production or action of prostaglandins and leukotrienes, thus limiting the renal damage caused by inflammation, platelet aggregation, and vasoconstriction.[24] In a controlled trial on patients with heavy proteinuria and mildly impaired renal function, daily use of fish oil delayed the progression of renal failure with modest reduction in proteinuria.[75] A metaanalysis of five controlled studies indicated that a minor, but not statistically significant, beneficial effect on renal function may be observed.[76] Results from several recent studies failed to confirm the beneficial effects reported earlier, and further studies are needed to confirm the role as well as the optimal dose. In many of the studies, 4 to 12 g/day were given for 2 or more years. Some of the fish oil preparations are rich in cholesterol; thus, it is appropriate to monitor the LDL cholesterol levels for patients receiving therapy.

ANGIOTENSIN-CONVERTING ENZYME INHIBITION

Because hypertension is a negative prognostic indicator of IgA nephropathy and many of these patients already have left ventricular diastolic malfunction despite being normotensive, early antihypertensive intervention with ACEIs or ARBs is important.[68,69] If a single agent is insufficient to reduce proteinuria and maintain blood pressure at 125/75 mm Hg, combined use of ACEI and ARB should be instituted.[70]

ALTERNATIVE THERAPEUTIC APPROACHES

Patients with IgA nephropathy have abnormal production of IgA and several different immunoglobulins. Immunoglobulins, administered intravenously initially and then intramuscularly, may have beneficial effects through immunomodulation, increased catabolism of autoantibodies, and blockade of receptors.[77] The doses in this experimental trial, which has not been independently replicated, were very high: 1 g/kg/day for 2 days IV for the first three months, then 0.35 mL/kg IM every 15 days for the next six months. Plasmapheresis with albumin replacement was performed before the 2- to 12-hour IV infusions to avoid serum sickness. Reduction in proteinuria, hematuria, GFR decline, and histologic activity index were observed for 11 patients with a progressive course of the disease. Renal survival was prolonged for eight of these patients who were followed for 3 to 10 years.[78] Larger, randomized, controlled trials are needed before one can recommend this regimen with confidence.

Urokinase, danazol, dapsone, sodium cromoglycate, and plasma exchange have also been evaluated, but none is consistently effective nor shown to affect renal function.[71,77] Cyclosporine treatment was found in a limited number of studies to reduce proteinuria; however, renal function decreased during treatment. Consequently, its use is limited by the potential for nephrotoxicity.[24,77]

The HMG-CoA reductase inhibitor fluvastatin was reported to reduce urinary protein excretion in moderately proteinuric (0.6 to 1.6 g/day) patients who had IgA nephropathy with normal renal function.[79] Creatinine clearance remained stable during the 6-month study. Although evaluation for a longer term in a larger patient population is needed to confirm this beneficial effect, statin use is an obvious choice for hyperlipidemic patients with IgA.

Antiplatelet agents are commonly used in Japan and rarely outside of Asia for IgA nephropathy.[80] A recent metaanalysis of seven trials (four in Japan and three in Hong Kong) revealed that these agents reduced proteinuria and stabilized renal function.[81] Mycophenolate mofetil and several new strategies are being evaluated as experimental treatments for IgA nephropathy on the premise that they may reduce IgA synthesis and mesangial uptake and/or suppress the effects of proinflammatory or profibrogenic mediators.[81]

Normotensive patients with normal renal function, isolated microhematuria, and proteinuria less than 1 g/day should be observed closely without specific treatment.[69] Patients with minimal proteinuria of 0.5 to 1 g/day receive fish oil and an ACEI or ARB (Fig. 56–6) to attain BP of <103/80 mmHg and urinary protein excretion of <500 mg/day.[24] Combined ACEI and ARB seems to be more effective than monotherapy. Because corticosteroids reduce proteinuria, a course of alternate-day prednisone (1 mg/kg/day) with subsequent tapering is indicated for patients with proteinuria greater than 3 g/day who have good renal function [>70 mL/min (>1.17 mL/s)].[71] A more aggressive IV or oral steroid regimen may be considered, even though its efficacy has not been definitively established. For patients with a slow progressive decline in creatinine clearance [<70 mL/min (<1.17 mL/s)], fish oil should be given. Azathioprine, cyclophosphamide, mycophenolate mofetil, or dipyridamole/warfarin therapy may also be used, although

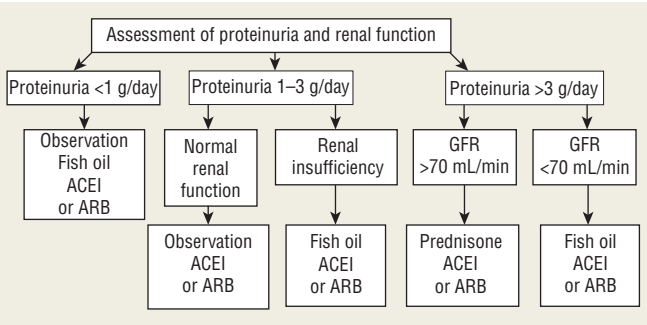

FIGURE 56-6. Treatment algorithm for biopsy-proven IgA nephropathy. (ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; GFR, glomerular filtration rate.) *(Modified from reference 71.)*

the efficacy of these agents has not been firmly established. If the patient experiences rapid GFR decline of more than 2 mL/min (0.033 mL/s) per month, immunoglobulin therapy may be considered despite the fact that only limited data are available. Other therapies that may be considered for these patients include pulse steroids, a cyclophosphamide–steroid combination, mycophenolate mofetil, and plasmapheresis.[24,69,71,82]

THERAPEUTIC OUTCOMES

Urinary protein excretion and the mean arterial blood pressure at follow-up correlate well with the progression of disease. The risk of developing ESRD is proportional to the amount of proteinuria, under the influence of ACEI and ARB therapy, after 1 year of follow-up.[83] For those patients who develop end-stage renal failure, transplantation is appropriate, especially for young adults. Recurrence of IgA mesangial deposits in the renal allograft may occur in up to 50% of patients in 5 years and be universally present at 10 years or more posttransplant, but the recurrence of clinical disease is only approximately 10% to 15%.[68,69] There is also no correlation between the aggressiveness of the primary disease and the rate of recurrence.[68] Use of ACEI may improve graft survival[84] while immunosuppression with corticosteroids, azathioprine, and/or cyclosporine is not expected to prevent the recurrent nephropathy.

LUPUS NEPHRITIS

Etiology and Epidemiology

Glomerulonephritis is one of the most serious complications of systemic lupus erythematosus (SLE) and accounts for much of the morbidity and mortality of patients afflicted with the disease. SLE predominantly affects young women between 15 and 40 years of age, with an incidence of 1 in 2,000 women in the United States. African Americans are more susceptible; they develop the disease at a younger age, have nephritis earlier in the course, and are more likely to progress to end-stage kidney disease.

The renal manifestations of lupus nephritis are variable and encompass a wide spectrum of histopathologic lesions.[85] The underlying histopathology is associated with different prognoses and responses to therapy, which can not be predicted solely based on clinical manifestations. Thus, a renal biopsy is required to assess the severity of the disease and to predict the short-term and long-term outcomes associated with therapy. Drugs, such as hydralazine and procainamide, are known to precipitate a lupus syndrome; however, they are unlikely to cause disease that affects the kidney.

Pathophysiology

Immune complex deposits, whether formed in the circulation or in situ, can be found in various regions of the glomerulus, as well as the peritubular interstitium and vasculature outside the glomerulus. Based on light, immunofluorescence, and electron microscopy findings, lupus nephritis can be categorized into six World Health Organization (WHO) classes: I, normal; II, mesangial; III, focal proliferative; IV, diffuse proliferative; V, membranous; and VI, advanced sclerosing.[86] In an attempt to enhance the predictive values of the histologic findings, semiquantitative assessments of active lesions and sclerotic changes are used to determine activity index and chronicity index, respectively. In 2003, the ISN/RPS (International Society of Nephrology/Renal Pathology Society) classification was developed to reduce interobserver reproducibility and provide a practical and standardized approach to biopsy interpretation so that outcome data can be compared worldwide.[87]

The hallmark feature in the pathogenesis of SLE is B-cell hyperactivity and the dysregulated production of autoantibodies against multiple antigens in the body, including DNA and various ribonucleoproteins.[85,88] The size and location of the immune complexes in the glomerulus correlate with the nature and severity of renal injury. Deposition of small numbers of stable immune complexes of intermediate size in the mesangium tends to produce less severe inflammation in the glomerulus. The sequestration of the immune complexes in the mesangium prevents them from activating inflammatory mediators. Hence, the lesion is noninflammatory in nature. In contrast, large numbers of intermediate-sized or large immune complexes result in infiltration of inflammatory cells and release of necrotizing enzymes.

Clinical Presentation

Females have a higher risk for developing lupus, especially in the adult years. Nephritis is commonly seen within the first 4 years of diagnosis of SLE but may also be the first manifestation of the disease. The clinical presentation ranges from minimal hematuria and proteinuria to severe, rapidly progressive diffuse glomerulonephritis. Proteinuria is very common, and nephrotic syndrome is seen in most patients with membranous lesions. Microscopic hematuria is almost always present, whereas macroscopic hematuria, which commonly indicates severe renal involvement, is rare.[86] Active urinary sediments (red cell casts, dysmorphic red cells, and hematuria) are suggestive of the diffuse proliferative lesion.[85] Hypertension is present in 25% to 45% of patients and is associated with a worse prognosis. Recent studies affirm the poor prognosis and higher risk for renal involvement among African-American and Texan-Hispanic patients, compared with white and Puerto Rican–Hispanic patients, due to the greater severity of disease at baseline, presence of certain autoantibodies, and socioeconomic considerations.[89] Other conditions found to be associated with poor prognosis include elevated serum creatinine concentration, heavy proteinuria, anemia [hematocrit <26% (<0.26)], and disease onset during childhood or in those >60 years of age. Most patients have hypocomplementemia and increased antibody titers for anti-double-stranded DNA, particularly those with focal or diffuse proliferative lesions. Serum creatinine concentration at the time of diagnosis is most predictive of short-term outcome.

TREATMENT

Lupus Nephritis

7 The choice of therapy depends on the underlying lesion and the activity, as well as the chronicity indices. Acute life-threatening disease involving multiple organs requires induction treatment that can suppress the disease promptly. In contrast, long-term management of chronic indolent disease requires therapy with more acceptable side-effect profiles. Corticosteroids are the cornerstone of therapy. However, for severe lupus nephritis, primarily the diffuse proliferative type, alkylating agents may be needed to reduce or prevent the progression to ESRD. Newer alternatives with fewer side effects are now available.

Optimal blood pressure control is important. ACE inhibitor or ARB has been shown to reduce proteinuria. Patients with normal renal function and less than 2 g of proteinuria usually do not require therapy, except for the management of extrarenal lupus manifestations. The prognosis of these patients is generally good, and renal biopsy can be delayed. However, close follow-up of renal function and urinalysis is required.

ACUTE INDUCTION TREATMENT

Steroids and Cytotoxic Agents

Patients with more than 2 g of proteinuria, deteriorating renal function, and/or active urinary sediments require a renal biopsy to define the underlying lesion and determine the activity and chronicity of disease. Patients with proliferative lesions, class IV and class III with subendothelial deposits and signs of severe disease activity, should be treated with pulse intravenous methylprednisolone followed by low-dose oral steroids. Cyclophosphamide is used concurrently because it is a powerful B-cell inhibitor and can suppress the resynthesis of autoantibodies to normal levels.[86] Combined use of intravenous cyclophosphamide and methylprednisolone is more effective than either agent alone in inducing remission.[88,90] Cyclophosphamide is given orally in some of the regimens.[91] Azathioprine has also been used in conjunction with cyclophosphamide. The risk for adverse events, such as infection, gonadal damage, amenorrhea, and cervical dysplasia, and malignancy is increased with the cytotoxic regimens.[88] Studies show that cyclophosphamide toxicities may be related to the cumulative doses rather than the route of administration.[91] Because oral doses of cyclophosphamide tend to accrue easily, it is prudent to use it only for those who are high risk and had failed other therapies.

Mycophenolate Mofetil

CLINICAL CONTROVERSY

Should mycophenolate mofetil be used in place of cyclophosphamide for lupus nephritis?

Several trials have found that mycophenolate mofetil with concurrent steroid therapy is an effective agent for induction therapy.[92] It was as effective as cyclophosphamide in inducing remission but with fewer side effects. A recent meta-analysis of the literature corroborates to the fact that it is an excellent agent for the induction of remission and that continued use may reduce risk for death or development of ESRD.[89] However, many of these trials were conducted in Asia, and the results may not be reproducible in American patients. Two recent trials that included African Americans, who are known to have a poorer prognosis, also show that mycophenolate mofetil was more efficacious than intravenous cyclophosphamide and resulted in fewer adverse effects.[88,93] Based on these data, mycophenolate mofetil seems to be a viable alternative to intravenous cyclophosphamide, especially for patients with mild to moderate focal or diffuse lupus nephritis or membranous lupus nephritis (WHO class III, IV, or V) and preserved renal function. However, the duration of follow-up in these trials was not as long as the trials that were conducted to establish the efficacy of cyclophosphamide-based regimens. The ability of mycophenolate mofetil to sustain the remission long term is still unclear (Fig. 56–7).

CHRONIC MAINTENANCE TREATMENT

Steroids and Cytotoxic Agents

Oral steroid is most frequently used for maintenance treatment (prednisolone 5 to 15 mg/day or equivalent).[86] Alternate-day regimens, although not evaluated, are often used in children to minimize growth retardation. Monthly pulse IV steroids in conjunction with cyclophosphamide resulted in more sustained remission, fewer relapses, and no significant increase in side effects.[94] Meta-analysis shows this combination to be more beneficial than steroid

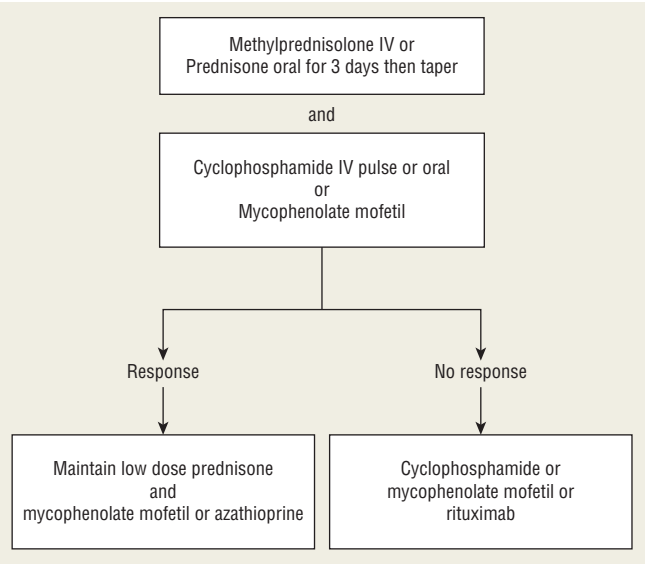

FIGURE 56-7. Treatment algorithm for proliferative lupus nephritis.

or cyclophosphamide alone. Cyclophosphamide, because of its bladder and gonadal toxicity, has been given as monthly and then bimonthly intravenous injection, instead of daily administration, for 2 or more years. However, toxicity is still a concern. A study conducted in Europe showed that after initial lower pulse doses of IV cyclophosphamide, oral azathioprine was able to attain remission rates similar to those of higher initial pulse doses of cyclophosphamide with quarterly follow-up doses.[95] Recently, daily doses of mycophenolate mofetil or azathioprine for 2 years have been shown to be more effective than intravenous pulses of cyclophosphamide in reducing relapse while being less toxic.[96]

Cyclosporine

Cyclosporine may reduce proteinuria and lupus activity, stabilize renal function, and improve kidney morphology. It has been shown to have comparable efficacy and safety with azathioprine in preventing relapse for patients with diffuse proliferative lupus nephritis.[97]

ALTERNATIVE THERAPEUTIC AGENTS

Many new agents have been developed to target the various pathways, costimulatory molecules, and immune mediators responsible for the pathologic autoantibody production.

LJP-394 (Riquent, abetimus sodium), composed of four double-stranded oligodeoxynucleotides, render specific B lymphocytes unresponsive to immunogen by cross-linking with the surface immunoglobulin receptors, thereby reducing anti-DNA antibody production. It may reduce renal and systemic SLE flares in a subgroup of patients whose anti-DNA antibodies are bound avidly to the compound.[98] However, a subsequent study did not reveal such a beneficial effect when compared with placebo.[88]

Rituximab is a monoclonal antibody directed against CD20, which is a membrane-associated glycoprotein on B lymphocytes. It causes B-lymphocyte depletion without affecting plasma cells, which do not have CD20. For patients, the B-cell depletion correlates with clinical response. The drug has been reported to have 75% response rate in refractory lupus or lupus nephritis. However, these studies are uncontrolled, and different regimens were used in heterogeneous groups of patients.[60,88] In the first randomized trial rituximab failed to show a superior response for patients receiving glucocorticoids and other background immunosuppressant therapy for remission induction in moderately to severely active nonrenal

lupus.[99] Results from ongoing randomized trials are needed to confirm its efficacy. Studies are also under way to evaluate epratuzumab (anti-CD22).

Disruption of communication between B and T cells can result in reduced autoimmune response. Different anti-CD40 ligand monoclonal antibodies, such as BG9588 (ruplizumab) and IDEC-131, have been evaluated; however, they were not found to be useful because of life-threatening thromboembolic complications.[100]

TREATMENT OUTCOME

The prognosis of patients with class II disease is generally good, and often no specific treatment is needed. For patients with class V disease, steroids alone commonly induce partial or complete remission. Immunosuppressive agents can be used for those who are not responsive to steroids. The survival of patients with classes III and IV disease has improved during the last two to three decades to approximately 74% to 80% at 10 years.[85] With the recent use of mycophenolate mofetil, better understanding of the optimal cytotoxic regimens, the use of lower steroid dosages, and better management of complications such as hypertension, infections, hyperlipidemia, and other metabolic complications of the disease, the long-term outcome has became more favorable. Lupus patients with end-stage kidney disease on dialysis fare as well as those with non-lupus–related renal disease. In those patients who received a renal transplant, the allograft outcome of patients with lupus nephritis is favorable and comparable to those without lupus. Recurrence of lupus in the renal allograft can occur but is usually of minor clinical importance.

RAPIDLY PROGRESSIVE GLOMERULONEPHRITIS

Etiology and Epidemiology

Rapidly progressive glomerulonephritis (RPGN) describes a clinicopathologic syndrome of rapid loss of renal function—usually a greater than 50% decrement of the GFR within 3 months. The predominant histologic finding of RPGN is extensive crescent formation, usually in more than 50% of the glomeruli. Hence, it is also known as *crescentic glomerulonephritis*. RPGN accounts for 2% to 7% of all renal biopsy findings and is responsible for up to 5% of patients with end-stage kidney disease. The age ranges of susceptible patients vary with the type of RPGN. For example, types I and II RPGN are more common in younger patients, whereas type III is seen more frequently in older individuals.

RPGN is not a single disease entity. A variety of glomerulonephritides with or without systemic diseases may present as RPGN, including anti-GBM glomerulonephritis, Goodpasture syndrome, lupus nephritis, poststreptococcal glomerulonephritis, membranoproliferative glomerulonephritis, IgA nephropathy, polyarteritis nodosa, Wegener granulomatosis, and idiopathic crescentic glomerulonephritis.

Primary RPGN is categorized according to the immunofluorescence microscopic findings, indicating different immunopathogenesis, therapeutic approaches, and clinical outcome. Type I is characterized by the linear localization of immunoglobulins, mainly IgG, along the GBM, signifying anti-GBM antibody-induced injury. Type II is defined by the coarse granular deposition of immunoglobulins and complement within the capillary walls and mesangium, indicating immune-complex–mediated injury. Type III is characterized by scanty or complete lack of immune complex deposits; consequently, it is also known as *pauci-immune RPGN*. Circulating ANCAs are often detected in type III RPGN.

Pathophysiology

Different etiologic factors are implicated as the cause of RPGN: toxins, drugs, viral and bacterial infections, neoplasms, autoimmune mechanisms, and various immunogenetic factors.[101] Regardless of the etiology and type of RPGN, damage in the glomerular capillary wall by both humoral and cellular pathways of inflammation is common. Activation of the terminal C5b-9 (membrane-attacking complex) of the complement system produces severe capillary wall injury. Proteinases and reactive oxygen species released by neutrophils and macrophages may result in severe glomerular injury. Platelets and the coagulation system are activated and result in capillary thrombosis. The ruptured capillaries release fibrinogen and procoagulants that may come into contact with thrombogenic tissue debris and lead to fibrinoid changes. In anti-GBM glomerulonephritis, the direct attack of the anti-GBM antibody on the GBM is responsible for the capillary wall injury.[101] For patients with ANCA-associated disease, the interaction of ANCAs with neutrophils and monocytes, which have been primed by concurrent infections or inflammatory processes, can lead to activation of these leukocytes and release of toxic oxygen species and lytic enzymes, resulting in vascular injury.

The disruption of the capillary wall allows movement of macrophages and other plasma constituents into Bowman space and stimulates the formation of crescents, which are composed mainly of parietal epithelial cells, as well as macrophages and fibroblasts. Crescent formation indicates the severity of the glomerular capillary disease but not its pathogenesis.

Clinical Presentation

Among the crescentic glomerulonephritides, the pauci-immune RPGN (type III) is the most frequent, accounting for more than 50% of cases, whereas the anti-GBM antibody-mediated RPGN (type I) is the least frequent, occurring in roughly 10% to 20% of patients. Of patients with type I RPGN, 60% to 70% may have concurrent pulmonary hemorrhage and Goodpasture syndrome, which is caused by antibodies directed against the pulmonary alveolar basement membrane. Most patients with immune-complex–mediated RPGN (type II) have collagen vascular disease, systemic infections, or a severe form of primary glomerular disease. Approximately 70% of patients with type III RPGN also present with evidence of systemic vasculitis, such as Wegener granulomatosis and polyarteritis nodosa. Some patients have only renal manifestations and are said to have idiopathic crescentic glomerulonephritis or renal vasculitis.

The clinical presentation is dominated by progressive renal insufficiency with complaints of tea-colored urine, malaise, anorexia, low-grade fever, and migratory polyarthropathy. Type I RPGN is more common in younger patients, whereas patients with ANCA-mediated disease tend to be older.[102] Urinalysis commonly shows nephritic sediments with hematuria, erythrocyte casts, and proteinuria. However, overt nephrotic syndrome is rare.

Serologic analysis is very useful in distinguishing the different types of RPGN. The detection of serum anti-GBM antibodies with the appropriate clinical presentation confirms the diagnosis of anti-GBM glomerulonephritis. More than 80% of patients with pauci-immune or idiopathic crescentic glomerulonephritis have circulating ANCAs. ANCAs are autoantibodies specific for the cytoplasmic constituents of neutrophil granules and monocyte lysosomes. Patients with ANCA-associated disease limited to renal involvement often have P-ANCA (perinuclear staining), whereas patients with Wegener granulomatosis tend to have C-ANCA (cytoplasmic staining). Both the anti-GBM antibody and the ANCAs are absent in patients with type II RPGN. Measurements of circulating immune complexes are not useful for making a specific diagnosis, but detection of specific serum antibodies known

to mediate immune complex–associated nephritis is helpful, using anti-DNA antibody as a marker for lupus nephritis and elevated antistreptolysin O titers for poststreptococcal glomerulonephritis.

TREATMENT

Rapidly Progressive Glomerulonephritis

Early aggressive therapy has improved the renal prognosis of patients with crescentic glomerulonephritis. The rapid deterioration of renal function and the paucity of a large number of patients make randomized controlled studies very difficult to conduct. Based on the available data, immunosuppressive therapy alone appears to be ineffective for type I RPGN, while types II and III RPGN respond well to high-dose steroid therapy.[101,103] Regardless of the type of RPGN, poor response to therapy and an ominous renal survival are expected if the patient presents with oliguria, has a serum creatinine concentration greater than 6 or 7 mg/dL (530 or 619 μmol/L), is dialysis dependent, or has a renal biopsy showing advanced chronic parenchymal disease.[104] Because of the differences in response, the therapeutic approaches for each type of RPGN are presented separately below.

ANTIGLOMERULAR BASEMENT MEMBRANE GLOMERULONEPHRITIS (TYPE I)

Steroids and cyclophosphamide, in conjunction with plasma exchange, have been used effectively to control the disease. Plasma exchanges remove the pathogenic anti-GBM antibodies in circulation and are conducted for 2 weeks or until the antibodies disappear. Steroids (prednisolone 1 mg/kg/day, tapered over 6 months) and cyclophosphamide (2 to 3 mg/kg/day for 3 months) are then given to prevent new antibody production.[102,103] Patients with mild disease generally respond well to plasma exchange alone or immunosuppression (steroid and/or cytotoxic agents). For patients with severe disease (poor renal function and extensive crescent formation), most are expected to respond to the combination of plasma exchange and steroid/cytotoxic drug therapy. Pulse intravenous administration of corticosteroids (methylprednisolone 30 mg/kg/day for 3 days) has been used successfully to alleviate pulmonary hemorrhage, but the results are not as convincing for glomerulonephritis.[101,103] Because of the rapid decline in renal function, diagnosis should be established early so that therapy can proceed without delay. When the serum creatinine concentration is 6 mg/dL (530 μmol/L) or above or the patient is oliguric or requires dialysis, the response to therapy is usually poor, and the patient should be treated conservatively.[102,103] Poor response should also be expected when crescents are found in more than 85% of the glomeruli.

IMMUNE-COMPLEX–MEDIATED GLOMERULONEPHRITIS (TYPE II)

Patients with postinfectious RPGN generally have a favorable prognosis even without treatment. Complete spontaneous recovery occurs in 50% of cases, whereas chronic renal failure develops in 32%.[101] Pulse doses of methylprednisolone (30 mg/kg/day, every other day × 3), followed by oral prednisone (1 mg/kd/day, tapered over several months) and then tapering, are beneficial in type II RPGN, with a response rate of 85% for patients with acute disease and 70% in those with more chronic disease.[101,103] Plasmapheresis does not appear to provide any additional benefit.[103]

ANTINEUTROPHIL CYTOPLASMIC AUTOANTIBODY-ASSOCIATED GLOMERULONEPHRITIS (TYPE III)

Combined use of high-dose corticosteroids and cyclophosphamide induces remission in more than 90% of patients.[104] Cyclophosphamide, if given intravenously, is associated with fewer infectious complications while being as effective as the oral route in inducing remission; however, the risk of relapse may be higher.[105] Because approximately 30% of the patients may relapse, cyclophosphamide also has been used for maintenance therapy. Mycophenolate mofetil and methotrexate are now being used, and they have been shown in limited studies to be effective.[103,105] Plasmapheresis is not expected to have any additional benefits for patients with mild to moderate disease who are receiving immunosuppressive therapy. However, as an adjunct to immunosuppressive therapy, it may be beneficial for patients with severe disease presenting with acute renal failure, especially those with pulmonary hemorrhage.[105]

RENAL TRANSPLANTATION

Anti-GBM nephritis may recur in up to 55% of patients who received a renal transplant. However, only 25% of these patients showed clinical disease activity, with rare allograft failure. Because the frequency of recurrence and its severity are related to the presence of circulating anti-GBM antibody, it is recommended that transplantation should not be performed until the anti-GBM antibody is undetectable for at least 6 to 12 months. The recurrence rate of ANCA-associated nephritis is 17%, with the average time to relapse from transplantation of 31 months.[106]

POSTSTREPTOCOCCAL GLOMERULONEPHRITIS

Etiology and Epidemiology

Poststreptococcal glomerulonephritis (PSGN) and glomerulonephritis caused by other infectious agents, such as bacteria, viruses, and parasites, were once common. Improved sanitation, personal hygiene, medical care, and public health measures helped to decrease the incidence of group A streptococcal infection both in the United States and in other developed countries, resulting in a decline of PSGN. In contrast, glomerulonephritis secondary to other infectious agents, such as hepatitis C and HIV, is seen with increasing frequency.

PSGN is now the most common form of glomerulonephritis in children but is less common than the other types of glomerulonephritis in adults. PSGN is seen mostly in children aged between 5 and 15 years and is uncommon in children younger than 2 years of age and in adults older than 50 years of age. It normally follows pharyngeal or skin infection caused by the nephritogenic strains of group A streptococci; however, other strains of streptococci, such as groups C and G, have also been reported to cause PSGN. Streptococcal pharyngitis is more common in winter and early spring, whereas skin infection is frequently found in the summer. The risk for developing acute glomerulonephritis secondary to the nephritogenic strains of bacteria is approximately 10% to 15% for infected patients. However, three to four times more patients may experience a subclinical form of the disease.

Pathophysiology

Streptococcal antigens may induce changes in the glomerular components rendering them immunogenic or autologous IgG may be altered to become antigenic. Alternately, the streptococcal antigens may induce antibodies that react with glomerular antigens. In situ

immune complexes are then formed and result in a complement-mediated inflammatory response. The kinin and coagulation cascades are activated, and chemotactic factors are released to recruit neutrophils and monocytes, resulting in acute glomerular lesions.

Examination of the acute PSGN kidneys reveals hypercellular glomeruli with proliferation of mesangial and endothelial cells. Infiltration of neutrophils, monocytes, and eosinophils is apparent within the capillary lumen and also in the mesangial areas. Crescent formation may be seen for patients with severe disease, and if found in more than 30% of the glomeruli, RPGN may be present concurrently.[107] The prognosis is generally poor for these patients, and complete recovery is unlikely. Immunofluorescence examination reveals diffuse granular deposits of IgG and C3 along the GBM and also in the mesangium.

Clinical Presentation

The nephritis is preceded by a latent period following a streptococcal infection. The latent period is commonly 7 to 14 days for pharyngitis and 14 to 28 days for skin infection. An acute nephritic syndrome then develops, commonly with hematuria and edema. Gross hematuria is seen in 70% of patients, and microscopic hematuria can be found in all patients. Hypertension is usually mild to moderate and results from sodium and water retention. Many patients have signs and symptoms associated with volume overload, which include dyspnea, orthopnea, and cough. Urinalysis of patients with PSGN reveals hematuria, dysmorphic red blood cells, and red cell casts. Proteinuria is common but often not in the nephrotic range. Renal function is frequently mildly impaired.

Throat or skin culture may be positive for group A streptococci, despite the latent period following the initial infection. However, antibiotic therapy may render the culture result negative. Serologic measurements of antibodies to different streptococcal antigens can confirm recent exposure to the infection. Titers that can be measured include antistreptolysin O (ASO), antistreptokinase, antihyaluronidase (AHase), antideoxyribonuclease B (ADNase B), and antinicotyladenine dinucleotidase (NADase).[108] For most patients with streptococcal pharyngitis, the ASO titers begin to rise about 10 to 14 days later, peak at 3 to 4 weeks, and persist for several months before decreasing. The rise in ASO titers can be reduced by antibiotic treatment and may not be seen for patients with streptococcal skin infection in whom the streptolysin may be bound to skin lipids. ADNase B and AHase titers should be used instead because they are specific and are positive in the majority of patients. The streptozyme test is a combined assay for ASO, ADNase B, NADase, and AHase. Antibodies to other antigens such as zymogen, streptococcal cationic proteinase exotoxin B (SPEB), and plasmin receptor (Plr) were evaluated recently.[109]

Serum complement levels are often decreased for patients with PSGN. If the C3 level is depressed for more than 6 to 8 weeks, MPGN, lupus nephritis, or glomerulonephritis related to endocarditis or occult visceral abscess should be suspected. Renal biopsy is not normally indicated unless the patient has prolonged hematuria, proteinuria, or depressed C3 level. Renal biopsy is needed to detect other types of glomerulonephritis such as lupus, RPGN, or MPGN.

TREATMENT

Poststreptococcal Glomerulonephritis

8 The treatment of PSGN is mainly supportive and symptomatic. Early antibiotic therapy does not prevent subsequent PSGN, but it may reduce the severity of the disease. It can, however, prevent the spread of the streptococcal infection to other family members. Antibiotic prophylaxis is not recommended because infected patients will develop long-lasting, often lifelong immunity against the strain of streptococci. Exposure to another nephritogenic strain of streptococci is possible, but unlikely.

Supportive measures should be used to control fluid volume and blood pressure. Because the hypertension is of the low-renin type, ACEIs and β-blockers are not expected to be useful. If the patient has crescentic disease, use of pulse steroids and/or immunosuppressive agents can be considered; however, the efficacy and safety of these agents have not been established for this condition.

The acute manifestations of PSGN are normally self-limited, and for more than 95% of patients renal function has returned to baseline within 3 to 6 weeks. Diuresis usually begins 7 to 10 days after onset of the acute episode, whereas hypertension and azotemia resolve in 1 to 2 weeks. Gross hematuria lasts for 1 to 2 weeks, and proteinuria usually resolves within 6 months in more than 90% of children. However, microscopic hematuria may persist for up to 2 years. In general, children have more rapid recovery than adults. Prognosis is often better when PSGN occurs during an epidemic than in cases found sporadically. Most of the children will recover fully and be free from chronic complications of PSGN if they have no preexisting renal disorder, heavy proteinuria, or crescentic glomerular lesions or did not require hospitalization during the acute episode. In contrast, adult patients have a less favorable long-term outcome. As many as 50% of the patients may develop persistent proteinuria, hypertension, and renal insufficiency, with some resulting in end-stage renal failure.

PHARMACOECONOMIC CONSIDERATIONS

Prospective, randomized, controlled comparative trials need to be conducted in a sizable patient population before the efficacy and economic implications of a new regimen can be established. This type of large-scale study is potentially feasible for the more common forms of glomerulonephritis, such as minimal-change disease, IgA nephropathy, and membranous nephropathy. In contrast, prospective controlled trials are difficult to conduct for the relatively uncommon glomerulonephritides such as membranous proliferative glomerulonephritis. After defining the natural history and the optimal drug regimen for each glomerulonephritis, in conjunction with the incidence of drug-induced complications, the economic implications of the individual treatment approach can be assessed. However, the optimal approaches for treating most types of glomerulonephritis have not been identified, and the economic implications of the individual treatment regimens thus remain to be established.

CONCLUSIONS

A better understanding of the pathogenetic mechanisms leading to glomerular injury has improved the treatment of glomerulonephritis. However, the glomerulopathies are a heterogeneous group of immune disorders with different clinical courses, prognoses, and responses to current immunologic and nonimmunologic therapies. The clinician should understand the natural history and prognosis of each subgroup of glomerulonephritis, the efficacy of different immunomodulation regimens in inducing disease remission and preserving renal function, and the characteristics of at-risk patients who warrant aggressive therapy. Judicious use of immunosuppressive agents with careful monitoring of their adverse effects cannot be overemphasized.

In addition, treatment of the disease complications and control of factors that lead to progression of renal disease are important in reducing the morbidity and mortality of patients with glomerulonephritis.

ABBREVIATIONS

ACE: angiotensin-converting enzyme

ADNase B: antideoxyribonuclease B

AHase: antihyaluronidase

ANCA: antineutrophil cytoplasmic autoantibody

ARB: angiotensin II receptor blocker

ASO: antistreptolysin O

ESRD: end-stage renal disease

GBM: glomerular basement membrane

GFR: glomerular filtration rate

FSGS: focal segmental glomerulosclerosis

HIV: human immunodeficiency virus

HMG-CoA: hydroxymethylglutaryl coenzyme A (reductase)

IL: interleukin

LDL: low-density lipoprotein (cholesterol)

MPGN: membranoproliferative glomerulonephritis

NADase: antinicotyladenine dinucleotidase

PSGN: poststreptococcal glomerulonephritis

RPGN: rapidly progressive glomerulonephritis

SLE: systemic lupus erythematosus

VLDL: very-low-density lipoprotein (cholesterol)

WHO: World Health Organization

CHAPTER 57

Drug Therapy Individualization for Patients with Chronic Kidney Disease

GARY R. MATZKE

KEY CONCEPTS

1. Chronic kidney disease has been demonstrated to result in minimal alterations in the absorption or bioavailability of only a few drugs.
2. The volume of distribution of many drugs is increased in the presence of acute and chronic kidney disease (CKD) as a consequence of volume expansion and reduced protein binding.
3. In addition to the expected decrement in renal clearance, nonrenal clearance (i.e., gastrointestinal and hepatic drug metabolism) of several drugs is also reduced in patients with CKD.
4. Individualization of a drug dosage regimen for a patient with reduced kidney function is based on the pharmacodynamic/pharmacokinetic characteristics of the drug and the patient's degree of residual renal function.
5. The drug dosing guidelines for patients with CKD in many drug information resources are highly variable and thus many are not optimal for clinical use.
6. The effect of hemodialysis or peritoneal dialysis on drug elimination is dependent on the characteristics of the drug and the dialysis prescription.
7. The application of hemodialysis clearance data to guide drug dosage regimen design for hemodialysis patients is limited and prospective monitoring of serum concentrations is often warranted.

Patients with chronic kidney disease (CKD) are commonly encountered in clinical practice. Indeed, it is estimated that nearly 15 million adults in the United States have serum creatinine values of 1.5 mg/dL (133 mmol/L) or greater.[1] In older adults, age-related declines in renal function combine with an increased use of medications to make this patient group particularly susceptible to adverse effects secondary to the lack of appropriate pharmacotherapy individualization.[2,3] The presence of a marked reduction in kidney function, whether it is an acute kidney injury (AKI) or CKD in any patient, necessitates that the clinician individualize drug therapy to maximize therapeutic outcomes.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

CKD is often accompanied by the development of anemia, hyperparathyroidism, hyperlipidemia, hypertension, and changes in gastrointestinal tract integrity (see Chapters 52 and 53). Thus CKD patients are often prescribed an extensive array of medications. There are now many reports that document changes in the disposition of some drugs in patients with CKD as the result of changes in bioavailability,[4,5] distribution volume,[6,7] and metabolic activity.[8–11] Thus drug therapy individualization is warranted for most patients with CKD. If a drug is predominantly renally eliminated unchanged, a dosage regimen adjustment may be calculated on the basis of the ratio of the patient's residual renal function relative to an age and gender normal value for estimated creatinine clearance or glomerular filtration rate.[12] However, for medications that are extensively metabolized or for which dramatic changes in protein binding and/or distribution volume have been noted, a more complex adjustment strategy may need to be employed.[7,13] Furthermore, because of the physiologic and biochemical changes associated with progressive CKD, patients may respond to a given dose or serum concentration of a drug differently than patients with normal renal function.[4]

Clinicians thus design individualized therapeutic regimens to optimize therapeutic outcomes and minimize adverse events, if they use basic pharmacokinetic principles combined with the drug's disposition properties and the patient's clinical characteristics. In this chapter, the influence of CKD on drug absorption, distribution, metabolism, and elimination is characterized. The array of drug information resources for the adjustment of the dosage regimens for patients with CKD is critiqued. A practical framework for drug dosage individualization for patients with CKD based on continuous versus categorical classifications is presented and the influences of peritoneal dialysis and hemodialysis on drug disposition are discussed. Finally, drug administration strategies for those receiving hemodialysis are presented. Drug dosage regimen adjustment strategies for patients with AKI, including those who are receiving continuous renal replacement therapy are presented in Chapter 51.

EFFECT ON DRUG ABSORPTION

1 There is little quantitative information regarding the influence of CKD on drug absorption and bioavailability. Changes in gastrointestinal transit time and gastric pH, edema of the gastrointestinal tract, vomiting and diarrhea (frequent complications of severe renal insufficiency), and antacid administration have all been proposed as a rationale for alterations in the bioavailability of drugs in CKD patients. Evaluations of bioavailability are generally conducted in those with severe stable renal insufficiency, that is, stage 5 CKD, which is also called end-stage renal disease (ESRD). The assessment of bioavailability in this patient population is,

however, complicated, because most of these patients are prescribed multiple medications (often in excess of 10 to 12 different agents), many of which cannot be discontinued during the course of a bioavailability study.

Many of the drug absorption so-called "bioavailability" studies in ESRD patients were not designed to provide an assessment of the drug's absolute bioavailability (i.e., they did not include a comparison of oral to intravenous administration of the drug). Rather, the principal outcomes were the documentation of alterations in the peak concentration (C_{max}), time at which the peak concentration was attained (t_{max}), or in the fractional amount of drug recovered in the urine in a finite time period. Unfortunately, this limited information has been extrapolated by some into a general conclusion that drug absorption is slowed and/or that the extent of absorption is reduced as the result of the development of CKD.[5]

In fact, the absolute bioavailability of only a few drugs is affected by ESRD and many of these are rarely used.[4,7] An increase in bioavailability as the result of a decrease in metabolism during the drug's first pass through the gastrointestinal tract and liver has been noted for some β-blockers (e.g., bufuralol, oxprenolol, propranolol, and tolamolol), dextropropoxyphene, and dihydrocodeine.[4,7] Although the bioavailability of these compounds is increased, clinical consequences (development of excessive or unexpected adverse effects) have only been demonstrated with dextropropoxyphene and dihydrocodeine.

EFFECT ON DRUG DISTRIBUTION

The volume of distribution of many drugs is increased in patients with moderate to severe CKD as well as those with preexisting CKD who develop AKI (Table 57–1).[7,14,15] This increase in distribution volume may be the result of decreased protein binding, increased tissue binding, or pathophysiologic alterations in body composition (e.g., fluid overload).

Generally, the plasma protein binding of acidic drugs (e.g., warfarin and phenytoin) is decreased in those with ESRD,[3,6,16] whereas the binding of basic drugs (e.g., quinidine and lidocaine) is usually normal or only slightly decreased or increased (Table 57–2).[3,6] The decrease in binding of acidic drugs has been attributed to qualitative changes in the binding sites, accumulation of endogenous inhibitors of binding, and/or decreased concentrations of albumin. The first two of these mechanisms appear to account for most of the observed changes in binding. In addition, the high concentrations of metabolites of some compounds that accumulate in patients with ESRD may compete for protein binding sites with the parent compound.

TABLE 57-1 Volume of Distribution of Selected Drugs in Patients with End-Stage Renal Disease

Drug	Normal (L/kg)	ESRD (L/kg)	Change from Normal (%)
Increased			
Amikacin	0.20	0.29	45
Azlocillin	0.21	0.28	33
Cefazolin	0.13	0.17	31
Cefoxitin	0.16	0.26	63
Cefuroxime	0.20	0.26	30
Clofibrate	0.14	0.24	71
Dicloxacillin	0.08	0.18	125
Erythromycin	0.57	1.09	91
Furosemide	0.11	0.18	64
Gentamicin	0.20	0.32	60
Isoniazid	0.6	0.8	33
Minoxidil	2.6	4.9	88
Nalmefene	7.9	14.7	86
Phenytoin	0.64	1.4	119
Trimethoprim	1.36	1.83	35
Vancomycin	0.64	0.85	33
Decreased			
Chloramphenicol	0.87	0.60	–31
Digoxin	7.3	4.0	–45
Ethambutol	3.7	1.6	–57

TABLE 57-2 Unbound Fraction of Selected Drugs in Patients with Normal Renal Function and End-Stage Renal Disease

Acidic Drugs	Normal	ESRD	Change from Normal (%)
Abecarnil	4	15	275
Azlocillin	63	75	20
Cefazolin	16	29	81
Cefoxitin	27	59	119
Ceftriaxone	10	20	100
Clofibrate	3	9	200
Dicloxacillin	3	9	200
Diflunisal	12	44	267
Doxycycline	12	28	133
Furosemide	4	6	50
Methotrexate	57	64	12
Metolazone	5	10	100
Moxalactam	48	64	33
Pentobarbital	34	41	21
Phenytoin	10	22	115
Salicylate	8	20	150
Sulfamethoxazole	34	58	71
Valproic acid	8	23	188
Warfarin	1	2	100
Basic Drugs	**Normal**	**ESRD**	**Change from Normal (%)**
Decreased			
Clonidine	56	48	–14
Disopyramide	32	28	–13
Propafenone	3	2	–29
Increased			
Amphotericin B	3.5	4.1	17
Chloramphenicol	45	64	42
Diazepam	2	8	300
Fluoxetine	5.5	6.5	18
Ketoconazole	1	1.5	50
Rosiglitazone	0.16	0.22	38
Triamterene	19	43	126

2 The unbound fraction of many acidic drugs increases in CKD patients as the result of a decrease in protein binding. A new equilibrium is ultimately established as a result of increased drug elimination/distribution, such that the unbound concentrations remain comparable to those observed in patients with normal renal function despite the fact that total concentrations are reduced. Thus, the net effect is an alteration in the relationship between total drug concentration and pharmacodynamic effect; it is commonly seen with the anticonvulsant phenytoin. The protein binding of this acidic drug, which binds to albumin, is significantly reduced and this change alters the relationship between total phenytoin concentration and desired effect as well as toxicity.[17] The resulting increase in unbound fraction, from values of 10% in those with normal renal function to ~20% or more in those with stage 5 CKD, results in increased hepatic clearance and decreased total concentrations. Thus, in patients with CKD, the therapeutic range based on total

phenytoin concentration is shifted downward from normal values of 10 to 20 mg/L (10–20 mcg/mL; 40–79 mmol/L) to values as low as 4 to 8 mg/L (4–8 mcg/mL; 16–32 mmol/L). Since the unbound concentration therapeutic range is the same for all patients, 1 to 2 mg/L (1–2 mcg/mL; 4–8 mmol/L), such a measurement provides the best target for individualizing phenytoin therapy in patients with CKD.

When unbound concentration measurements are not clinically available, one can approximate the equivalent "total" phenytoin concentration in an ESRD patient relative to an individual with normal renal function.[17] Although these approaches have not been rigorously evaluated, they may be useful in some clinical settings to predict dosage requirements.

The principal binding protein for several basic drugs is α_1-acid glycoprotein, an acute-phase reactant protein whose plasma concentrations are increased in CKD patients.[3,7] As a result of this increase, the unbound fraction of some basic drugs may be significantly decreased in ESRD patients.

Altered tissue binding may also affect the apparent volume of distribution of a drug. For example, the distribution volume of digoxin has been reported to be reduced by 30% to 50% from normal values in patients with stage 5 CKD, as well as in hemodialysis patients.[18] This reduction in the distribution volume may be secondary to a decrease in tissue binding as a result of competitive inhibition by endogenous or exogenous substances. Acidosis or the presence of digoxin-like immunoreactive substances that bind to and inhibit membrane adenosine triphosphatase may also contribute to this phenomenon.[19] In this situation, the absolute amount of digoxin bound to the receptor is reduced and the resultant serum digoxin concentration is higher than anticipated. Multiple methods have been proposed to estimate the degree of reduction in digoxin's distribution volume.[18]

Thus, in patients with renal insufficiency, particularly in those with stage 5 CKD, a "normal" total drug concentration may be associated with either an adverse reaction secondary to elevated unbound drug concentrations, or a subtherapeutic response because of an altered plasma-to-tissue drug concentration ratio. The monitoring of unbound drug concentrations in CKD patients is thus warranted for those drugs that have a narrow therapeutic range, are highly protein bound (free fraction of <20%), and for which marked variability in the free fraction has been reported (e.g., phenytoin and disopyramide).

Finally, the method used to calculate the volume of distribution may be influenced by renal insufficiency. The three most commonly used volume of distribution terms are: volume of the central compartment (V_c), volume of the terminal phase (V_β and V_{area}), and volume of distribution at steady state (V_{ss}). The V_c for many drugs approximates extracellular fluid volume and thus may be increased or decreased by acute changes. Oliguric acute renal failure is often accompanied by fluid overload and a resultant increased V_c for many drugs. The V_{area} or V_β represents the proportionality constant between plasma concentrations in the terminal elimination phase and the amount of drug remaining in the body. V_β is affected by both distribution characteristics, as well as by the terminal elimination rate constant. V_β and V_{ss} will often be similar in magnitude, with V_β being slightly larger. Because V_{ss} has the advantage of being independent of drug elimination, it is the most appropriate volume term to use when one desires to compare drug distribution volumes between patients with renal insufficiency and those with normal renal function.[21]

EFFECT ON METABOLISM

3 A decrease in the renal clearance of drugs in patients with CKD is well appreciated. However, there is now good preclinical and emerging clinical evidence that CKD may lead to alterations in nonrenal clearance of many medications as the result of alterations in the activities of uptake and efflux transporters as well as cytochrome P450 (CYP) enzymes in the liver and other organs[8–11,22,23] (Table 57–3). However, the effect(s) of renal insufficiency on nonrenal drug clearance also appears to depend on whether the reduction in renal function is acute or chronic in nature. The degree of reduction in those with AKI does not appear to be as great as that observed in ESRD patients.[14]

TABLE 57-3 Nonrenal Clearance of Many Drugs is Reduced in Patients with End-Stage Renal Disease

Acyclovir	Guanadrel	Repaglinide
Aztreonam	Imipenem	Rosuvastatin
Bufuralol	Isoniazid	Roxithromycin
Bupropion	Ketoprofen	Simvastatin
Captopril	Ketorolac	Telithromycin
Carvedilol	Lomefloxacin	Valsartan
Cefipime	Losartan	Vancomycin
Cefmetazole	Lovastatin	Verapamil
Cefonicid	Metoclopramide	Zidovudine
Cefotaxime	Minoxidil	
Ceftriaxone	Morphine	
Ceftizoxime	Nicardipine	
Cervistatin	Nimodipine	
Cilastatin	Nitrendipine	
Cimetidine	Nortriptyline	
Ciprofloxacin	Procainamide	
Didanosine	Quinapril	
Didanosine	Quinapril	
Encainide	Reboxetine	
Erythromycin	Raloxifene	

Although the early studies should be interpreted with caution because concurrent drug intake, age, smoking status, and alcohol intake were often not well controlled, those published in the last few years provide strong evidence of a significant independent effect of CKD on drug metabolism, predominantly for those drugs which are metabolized by CYP3A4[9] (Table 57–4). CYP3A activity as measured by the erythromycin breath test (EBT) is 28% lower in ESRD patients as compared with healthy controls.[24] Although baseline CYP3A activity was lower in these patients, the increase in CYP3A activity observed following enzyme induction with rifampin was similar.[24] Nolin and colleagues have recently shown that EBT results are reduced more in those ESRD patients with higher blood urea nitrogen concentrations and that hemodialysis is associated with an acute improvement in the patient's metabolic activity.[9] These data indicate that CKD has a detrimental effect on this important pathway of hepatic drug metabolism in humans.

Prediction of the effect of renal insufficiency on the metabolism of a particular drug is however difficult and there is currently no quantitative strategy to predict changes for one drug based on data from another in the same class. However, some qualitative insight can be gained if one knows what enzyme is involved in the metabolism of the drug of interest and how the enzyme(s) or transporter(s) is affected by the presence of CKD.

Investigations of the effect of chronic renal failure on hepatic enzyme activity in animals have demonstrated reductions in some, but not all, pathways of drug metabolism.[9,22,23] The mechanism(s) by which CKD affects hepatic drug metabolism is not clearly known, but may relate to accumulation of endogenous inhibitors (e.g., uremic toxins) or to the fact that CKD patients exist in a chronic inflammatory state and have increased levels of oxidative stress,[25] and other factors known to downregulate CYP enzymes.[26] In rat models of chronic renal failure, protein expression of several CYP enzymes, including CYP3A1 and CYP3A2 (corresponding to human CYP3A4), is reduced in the liver by as much as 75%. The mechanism of this decrease in protein content and messenger ribonucleic acid

TABLE 57-4 Drugs which are Predominantly Metabolized for which a Decrease in Nonrenal Clearance has been Observed in CKD Patients

Drug	Renal Function	CL_{total} [a]	CL_{renal} [a]	$CL_{nonrenal}$ [a]	Metabolic Pathway(s)
Cibenzyline	Normal	707 mL/min	344	363	CYP2D6, CYP3A4
	ESRD	224	0	224	
Cyclophosphamide	Normal	79 mL/min	15	64	CYP2B6, CYP2C9, CYP3A4,
	CKD	47	2.4	44.6	
Felbamate	Normal	0.5 mL/min/kg	0.15	0.35	CYP2E1, CYP3A4
	CKD	0.25	0.02	0.23	
Reboxetine	Normal	37 mL/min	3	34	CYP3A4
	CKD	12	1	11	
Roxithromycin	Normal	48.8 mL/min	5.5	43.3	CYP3A4
	CKD	25.4	0.4	25.0	
Telithromycin	Normal	79.2 L/h	9.3	69.9	CYP3A4
	CKD	50.0	2.6	47.4	

[a]Clearance in mL/min can be converted to mL/s through multiplication by 0.0167.

expression suggests transcriptionally mediated downregulation or post-translational inhibition of the metabolic pathway.[9,22]

Thus, current data suggest a differential effect on the individual CYP enzymes with the activity of some enzymes (e.g., CYP3A4 and CYP2C9) being reduced, while others (e.g., CYP2E1) are not affected.[9,10] This differential effect on individual enzymes may help to explain some of the conflicting reports of whether drug metabolism is altered in the presence of CKD.

EFFECT OF RENAL INSUFFICIENCY ON METABOLITE ELIMINATION

Patients with severe renal insufficiency who are receiving chronic treatment with some agents may experience accumulation of metabolite(s) as well as parent compound. Metabolites of several drugs have been reported to have significant pharmacologic and/or toxicologic activity. However, the pharmacokinetics and pharmacodynamics of metabolites are not often fully elucidated. In a sense, the patient with severe CKD is being exposed to a new pharmacologic entity since the sum of the serum concentrations of the metabolite and the parent compound are markedly different than those reported in patients with normal renal function.

The metabolite may have pharmacologic activity similar to that of the parent drug and thus contribute significantly to clinical response; that is true, for example, of oxypurinol. Alternatively, the metabolite may have qualitatively dissimilar pharmacologic action; for example, normeperidine has central nervous system (CNS) stimulatory activity that reportedly produces seizures, whereas meperidine has CNS depressant actions.[27] Because of the multiplicity of potential interactions of compounds that are primarily metabolized, the practical consequences of metabolite accumulation are difficult to predict and are most often identified in those patients at risk by trial and error.

EFFECT OF CKD ON RENAL DRUG EXCRETION

Renal clearance (CL_R) of a drug is the composite of GFR, tubular secretion, and reabsorption [$(CL_R = (GFR \times f_u) + (CL_{secretion} - CL_{reabsorption})$], where f_u is the fraction of the drug unbound to plasma proteins. Drug elimination by filtration occurs by diffusion; while tubular secretion and reabsorption are bidirectional processes that involve carrier-mediated renal transport systems.[28] Renal transport systems have been broadly classified on the basis of substrate selectivity into the anionic and cationic renal transport systems, which are responsible for the transport of a number of organic acidic and basic drugs, respectively (see Chapter 50). Renal organic anion transport is mediated by transporters, transporting polypeptides, and multidrug resistance-associated protein transporters.[29] Several drugs, including β-lactam antibiotics, diuretics, and nonsteroidal antiinflammatory drugs, are actively secreted by one or more of these transporter families which also have an essential role in the elimination of glucuronide metabolites. Organic cation transport systems mediate the reabsorption and excretion of endogenous cationic compounds and drugs (e.g., cimetidine, famotidine, and quinidine). The P-glycoprotein transport system in the kidney is also involved in the secretion of cationic and hydrophobic drugs (e.g., digoxin and vinca alkaloids).[29] Other important renal transport systems include the peptide transporters, which are involved in the uptake of peptide-like drugs including β-lactam antibiotics and angiotensin-converting enzyme inhibitors, while nucleoside transporter proteins are involved in uptake of nucleosides and nucleoside analogs (e.g., zidovudine and dideoxyinosine).

Alterations in filtration, secretion, or reabsorption, secondary to CKD may have a dramatic effect on drug disposition: for drugs that are primarily filtered, a reduction in glomerular filtration rate will result in a proportional decrease in renal drug clearance. However, for drugs that are extensively renally secreted (CL_R >300 mL/min [>5.00 mL/s]), the loss of filtration clearance (up to 120 mL/min [2.00 mL/s]) will have less of an impact. In the absence of data delineating the contribution of tubular function to renal clearance, the clinical measurement or estimation of creatinine clearance remains the guiding factor for drug dosage regimen design.[7,12] The importance of an alteration in renal function on drug elimination depends on two factors: the fraction of drug normally eliminated by the kidney unchanged and the degree of renal insufficiency. Quantitation of the patient's renal function can be accomplished by measurement of CL_{cr} or GFR or estimation of CL_{cr} or GFR based on the stable serum creatinine concentration (see Chapter 50). Because of the time delay involved and problems in obtaining complete urine collections, measured CL_{cr} or GFR values are infrequently used for initial drug dosage regimen design. Therefore the calculation of initial drug dosage regimens relies on the estimation of CL_{cr} or GFR in adults and children from such routinely available clinical data as age, gender, height, weight, and serum creatinine. Although several methods have been proposed to estimate GFR from routinely available clinical data (see Chapter 50) the usefulness of an estimated GFR (eGFR) to guide drug dosing has only recently been extensively evaluated.[30–33] The results of these investigations have yielded controversial findings and future prospective studies of the relationship between estimated CL_{cr} and GFR and the total body clearance of medications will likely be needed to resolve this issue. At the present time the use of CL_{cr} is preferred but the use of eGFR is likely better than not

TABLE 57-5 Stepwise Approach to Adjust Drug Dosage Regimens for Patients with Renal Insufficiency

Step 1	Obtain history and relevant demographic/clinical information	Record demographic information, obtain past medical history including history of renal disease, and record current laboratory information (e.g., serum creatinine)
Step 2	Estimate creatinine clearance	Use Cockcroft-Gault equation to estimate creatinine clearance, or calculate creatinine clearance from timed urine collection
Step 3	Review current medications	Identify drugs for which individualization of the treatment regimen will be necessary
Step 4	Calculate individualized treatment regimen	Determine treatment goals (see text); calculate dosage regimen based on pharmacokinetic characteristics of the drug and the patient's renal function
Step 5	Monitor	Monitor parameters of drug response and toxicity; monitor drug levels if available/applicable
Step 6	Revise regimen	Adjust regimen based on drug response or change in patient status (including renal function) as warranted

considering the potential influence of CKD on drug dosage regimen design. These relationships are most accurate for individuals of average muscle mass for their age, weight, and height. The CL_{cr} and eGFR of emaciated and obese adult patients is difficult to predict, and incorrect estimates have been obtained with most methods.

Several methods are also available for estimating creatinine clearance in adults with acute renal failure using age, height, weight, serum creatinine, and time data (see Chapter 50). These methods have not been independently validated and their usefulness for approximating renal function in complex patient situations is not currently recommended.

DRUG DOSAGE REGIMEN DESIGN FOR PATIENTS WITH CHRONIC KIDNEY DISEASE

4 An approach for designing a dosage regimen for a patient with CKD is depicted in Table 57–5. The design of the optimal dosage regimen is dependent on the availability of an accurate characterization of the relationship between the pharmacokinetic parameters of the drug and renal function and an accurate assessment of the patient's renal function (CL_{cr}). Prior to 1998 there was no consensus regarding the explicit criteria for characterization of the relationship between the pharmacokinetics and pharmacodynamics of a drug and renal function. The U.S. Food and Drug Administration (FDA) industry guidance issued in May 1998[34] and the European Medicines Agency guidance of 2004[35] provided a framework to help companies decide when they should conduct such a "characterization" study and proposed explicit recommendations for study design, data analysis, and assessment of the impact of the study results on drug dosing. Thus the quality of data available to clinicians has improved dramatically in the last 10 years. A new draft FDA guidance was proposed in 2010 and characterization of the influence of CKD on the pharmacokinetics and pharmacodynamics of a broader range of medications, including many that are predominantly metabolized, is now recommended.[36] The availability of this critical information for many new medications will increase the proportion of patients for whom drug dosage individualization will then be practical.

Most dosage-adjustment guidelines have proposed the use of a fixed dose or interval for patients with broad ranges of renal function that are different from those that are the foundation of the CKD staging scheme (see Chapter 52).[3,13,15,29,37–39] Indeed, normal renal function has often been ascribed to anyone who has a CL_{cr} >80–90 mL/min (>1.34–1.50 mL/s), even though the population normal CL_{cr} values range from 115 to 125 mL/min/1.73 m^2 (>1.11–1.20 mL/s/m^2). Mild renal insufficiency encompasses the range of 60 to 89 mL/min (1.00–1.49 mL/s), moderate renal insufficiency the CL_{cr} range of 30 to 59 mL/min (0.50–0.99 mL/s), while severe renal insufficiency and ESRD often are defined as a CL_{cr} of 15 to 29 mL/min (0.25–0.49 mL/s) and <15 mL/min (<0.25 mL/s), respectively. Each of these categories encompasses a broad range in renal function, and thus the calculated drug regimen may not be optimal for all patients whose renal function lies within the given category of renal function.

5 Secondary references, such as the American Hospital Formulary Service Drug Information Service,[37] the British National Formulary,[38] and Drug Prescribing in Renal Failure,[39] are generally touted as excellent sources of information about a drug's pharmacokinetic characteristics in subjects with normal and impaired renal function. A recent analysis of several of these sources suggests a need for a consistent quantitative approach to drug dosage regimen individualization for those with CKD.[40] The authors concluded that the remarkable variation in recommendations along with the paucity of details of the methods used to generate the dosing advice made these sources of drug information less than optimal for clinical use. None of these sources consistently provide the explicit relationships of the kinetic parameters of interest (total body clearance, elimination rate constant, and distribution volume) with a continuous index of renal function, such as CL_{cr}. To find this information, one may need to identify the original research study that assessed the drug's disposition or a comprehensive review article on the class of drugs of interest. This is a time consuming process that may be difficult to carry out for each drug and patient combination in real time. Ideally, one should be able to identify a relationship between total body clearance (CL) or elimination rate constant (k) with an eGFR or CL_{cr}, such as those depicted in Table 57–6. This information, along with the patient's estimated CL_{cr} or GFR is the foundation upon which one can formulate a therapeutic regimen to attain the desired therapeutic outcome.

If specific literature recommendations and/or the relationship of kinetic parameters to eGFR or CL_{cr} are not available, then one can estimate the CL or k of the patient with the method of Rowland and Tozer,[12] provided the fraction of the drug that is eliminated renally unchanged (f_e) in subjects with normal renal function is known.[14]

TABLE 57-6 Relationship Between Creatinine Clearance and Total-Body Clearance and Terminal Elimination Rate Constant of Selected Drugs

Drug	Elimination Rate Constant	Total Body Clearance[a]
Acyclovir		$CL = 3.37\ (CL_{cr}) + 0.41$
Amikacin	$k = (0.0024 \times CL_{cr}) + 0.01$	$CL = 0.6\ (CL_{cr}) + 9.6$
Aztreonam		$CL = 0.8\ (CL_{cr}) + 26.6$
Cefazolin	$k = (0.0028 \times CL_{cr}) + 0.022$	$CL = 0.34\ (CL_{cr}) + 6.6$
Ceftazidime	$k = (0.004 \times CL_{cr}) + 0.004$	$CL = 1.15\ (CL_{cr}) + 10.6$
Ciprofloxacin		$CL = 2.83\ (CL_{cr}) + 363$
Digoxin		$CL = 0.88\ (CL_{cr}) + 23$
Gentamicin	$k = (0.0029 \times CL_{cr}) + 0.015$	$CL = 0.983\ (CL_{cr})$
Imipenem		$CL = 1.42\ (CL_{cr}) + 54$
Lithium		$CL = 0.20\ (CL_{cr})$
Ofloxacin		$CL = 1.04\ (CL_{cr}) + 38.7$
Piperacillin	$k = (0.0049 \times CL_{cr}) + 0.21$	$CL = 1.36\ (CL_{cr}) + 1.50$
Tobramycin	$k = (0.0029 \times CL_{cr}) + 0.01$	$CL = 0.801\ (CL_{cr})$
Vancomycin	$k = (0.00083 \times CL_{cr}) + 0.0044$	$CL = 0.69\ (CL_{cr}) + 3.7$

CL, total-body clearance; CL_{cr}, creatinine clearance.
[a]Clearance in mL/min can be converted to mL/s through multiplication by 0.0167.

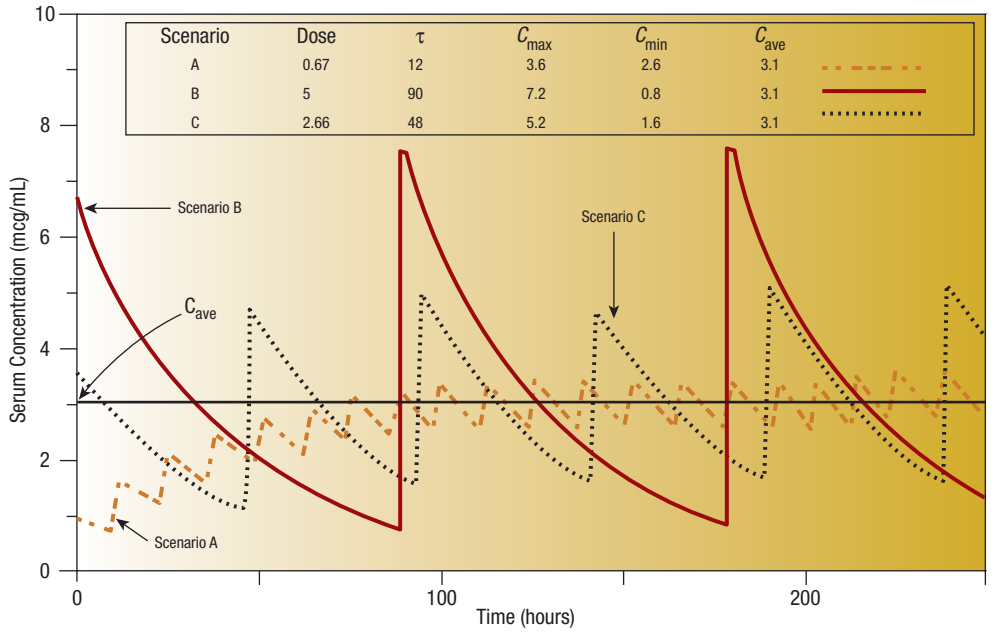

FIGURE 57-1. Although the average steady-state concentrations (C_{ave}) are identical regardless of which dosage-adjustment strategy one decides to implement, the concentration–time profile will be markedly different if one changes the dose and maintains the dosing interval (τ) constant *(Scenario A)*, versus changing the dosing interval and maintaining the dose constant *(Scenario B)* or changing both *(Scenario C)*.

This approach assumes that the change in CL and k are proportional to CL_{cr}, that renal disease does not alter the drug's metabolism, that the metabolites, if formed, are inactive and nontoxic, that the drug obeys first-order (linear) kinetic principles, and that it is adequately described by a one-compartment model. If these assumptions are true, then the kinetic parameter/dosage-adjustment factor (Q) can be calculated as:

$$Q = 1 - [f_e(1 - KF)]$$

where KF is the ratio of the patient's CL_{cr} to the assumed normal value of 120 mL/min (equivalent to 2.00 mL/s). Thus for a drug that is 85% eliminated renally unchanged in a patient who has a CL_{cr} of 10 mL/min (0.17 mL/s), the Q factor would be:

$$\begin{aligned} Q &= 1 - [0.85(1 - (10/120))] \\ &= 1 - [0.85(0.92)] \\ &= 1 - 0.78 \\ &= 0.22 \end{aligned}$$

The best method for dosage regimen adjustment must then be selected. Specifically, one must determine whether the desired goal is the maintenance of a similar peak, trough, or average steady-state drug concentration. If there is a significant relationship between peak concentration and clinical response[41] (e.g., aminoglycosides) or toxicity[42] (e.g., quinidine, phenobarbital, and phenytoin), then attainment of the specific target values is critical. If, however, no specific target values for peak or trough concentrations have been reported (e.g., antihypertensive agents and benzodiazepines), then a regimen goal of attaining the same average steady-state concentration may be appropriate.

Although several methods have been proposed to attain the desired average steady-state concentration profile, the principal choices are to decrease the dose or prolong the dosing interval. If the size of the dose is reduced while the dosing interval remains unchanged, the desired average steady-state concentration will be similar; however, the peak will be lower and the trough higher (Fig. 57–1). Alternatively, if the dosing interval is increased and the dose size remains unchanged, the peak and trough concentrations in the patient with reduced renal function will be similar to those in the patient with normal renal function. This dosage adjustment method is often recommended because it is likely to yield cost savings as a result of a reduction in nursing and pharmacy time, as well as a reduction in the supplies associated with frequent drug administration. Finally, the dose and dosing interval may both need to be changed to allow the administration of a clinically feasible dose (500 mg vs a calculated value of 487 mg) or a practical dosing interval, for example, 12 hours instead of 17 hours.

If the relationship between the pharmacokinetic parameters of the drug and renal function are known, the first step in the process is to estimate the drug disposition parameters in the patient with renal insufficiency. The dosage-adjustment factor (Q) can then be calculated as the ratio of the estimated elimination rate constant or total body clearance of the patient relative to subjects with normal renal function (CL_{cr} = 120 mL/min [2.00 mL/s]). This parameter may be used to determine the dose or dosing interval alterations necessary for the patient.

For example, the following relationship between total-body clearance (CL) and creatinine clearance (expressed in conventional units of mL/min) has been reported for ganciclovir:[43]

$$CL(mL/min/1.8\ m^2) = 1.25(CL_{cr}) + 8.57$$

Thus, CL for a subject with normal renal function (CL_{norm}) would be calculated as:

$$\begin{aligned} CL_{norm} &= [1.25(120)] + 8.57 \\ CL_{norm} &= 158.6\ mL/min\ per\ 1.8\ m^2 \end{aligned}$$

Clearance (CL_{fail}) for a patient with a creatinine clearance of 10 mL/min would be:

$$\begin{aligned} CL_{fail} &= [1.25(10)] + 8.57 \\ CL_{fail} &= 21.1\ mL/min\ per\ 1.8\ m^2 \end{aligned}$$

Ganciclovir is commonly used in solid-organ transplantation patients as prophylaxis against or treatment for cytomegalovirus infection.[44] The inhibitory concentration (IC_{50}) of ganciclovir against 50% of clinical isolates of cytomegalovirus ranges from approximately 0.1 - 2.8 mg/L (0.4 to 11 mmol/L).[43] Consequently, trough concentrations should be maintained within this range, but caution is warranted as neutropenia has been associated with the attainment of ganciclovir trough concentrations exceeding 2.6 mcg/mL (2.6 mg/L; 10 mmol/L).[45] If a patient with ESRD received the ganciclovir dose intended for a patient with normal renal function, the predicted trough concentrations would approach 5.2 mcg/mL (5.2 mg/L; 20 mmol/L). Consequently, a dosage modification would be necessary to avoid potential toxicity. The dosing regimen can be modified using the ratio of the predicted clearance values. The quotient or Q for this patient can be calculated as:

$$Q = CL_{fail}/CL_{norm}$$
$$Q = 21.1/158.6$$
$$Q = 0.133$$

where CL_{norm} is the clearance in a patient with normal renal function and CL_{fail} is the clearance of the patient with impaired renal function.

The maintenance dose (D_f) for the patient or the adjusted dosing interval (τ_f) may then be calculated from the following relationships, where D_n is the normal dose and τ_n is the normal dosing interval:

$$D_f = D_n \times Q$$
$$\tau_f = \tau_n/Q$$

For this patient situation, the normal dose and dosing interval of ganciclovir would be 5 mg/kg and 12 hours, respectively. If we wanted to maintain the dosing interval at 12 hours, then D_f would be calculated as:

$$D_f = (5 \text{ mg/kg}) \times (0.133) = 0.67 \text{ mg/kg}$$

This regimen would result in decreased peak and trough concentrations compared to a patient with this degree of renal insufficiency who received a normal dosage regimen (Fig. 57–1, Scenario A). However, the peak concentrations would be lower and the trough concentrations higher than those observed when a patient with normal renal function received a standard regimen.

If one maintains D_n and extends the dosing interval, τ_f would be calculated as:

$$\tau_f = \tau_n/Q = 12/0.133 = 90 \text{ hours}$$

This regimen would yield similar peak and trough concentrations in the renally impaired patient as in the patient with normal renal function, but there is a risk of missed doses with such an unorthodox interval (Fig. 57–1, Scenario B). In addition, the prolonged period below the steady-state drug concentration (C_{ss}) average concentration may be less than optimal.

Finally, a practical dosing interval (τ_p) may be selected and then a dose based on that interval can be calculated. If a dosage interval τ_f of 24 hours were selected, because in many institutions there is an increased risk of missed doses with longer dosing intervals, then the D_f would be calculated as follows:

$$D_f = [D_n \times Q \times \tau_f]/\tau_p$$
$$= [(5 \text{ mg/kg}) \times (0.133) \times (24)]/12$$
$$= 1.33 \text{ mg/kg}$$

This method would be most appropriate, as prolonged subtherapeutic concentrations are avoided and troughs are reduced (Fig. 57–1, Scenario C). The selection of which dosage-adjustment method to use to calculate an optimal regimen depends on the drug characteristics and the patient care situation. This dosage-adjustment method assumes that the protein binding and volume of distribution of the drug are not significantly altered by renal insufficiency. Thus, this approach cannot be used with accuracy for those drugs with demonstrated differences in these pharmacokinetic parameters.

If the volume of distribution (V_D) of a drug is significantly altered in CKD patients or in whom one desires to attain a specific maximum or minimum concentration, the estimation of a dosage regimen becomes more complex. If the relationship between V_D and CL_{cr} has been characterized, then V_D may be estimated. If one assumes that a one-compartment linear model can describe the drug, the predicted V_D may then be used with the predicted elimination rate constant (k) of the drug to yield an adjusted-dosing interval and intravenous or oral dose. For orally administered drugs, the τ_f can be calculated and the dose can then be approximated as:

$$\tau_f = [(-1/k_f)(\ln[C_{min}/C_{max}])] + t_{peak}$$
$$Dose_{po} = [FC^t_p V_D(k_a - k)]/[k_a(e^{-kt}/1 - e^{-k\tau})(e^{-kat}/1 - e^{-ka\tau})]$$

where, F equals bioavailability, C^t_p equals the desired plasma concentration at time t, and k_a is the absorption rate constant. This approach allows for the individualization of an oral dosage regimen for attainment of specific peak and trough serum concentrations. If the drug is absorbed extremely rapidly, one can approximate the τ_f and the dose using equations originally proposed for IV dosing as:

$$\tau_f = (-1/k_f)(\ln[C_{min}/C_{max}])$$
$$Dose_{po} = V_D \times (C_{max} - C_{min})$$

Digoxin is a frequently used oral medication for which the V_D is decreased in CKD patients and for which one usually desires to closely control the plasma concentration time profile. The V_D and CL_{fail} of digoxin can be estimated for a 70-kg (154 lb) patient with a CL_{cr} of 12 mL/min per 1.73 m^2 (0.11 mL/s/m^2) as summarized by Job[18]:

$$V_D = 226 + [(298(CL_{cr}))/(29.1 + CL_{cr})]$$
$$= 226 + [(298(12))/(29.1 + 12)]$$
$$= 226 + 87.0$$
$$= 313 \text{ L}$$
$$CL_{fail} = (0.88 \times CL_{cr}) + 23 \text{ mL/min}$$
$$= 10.6 + 23$$
$$= 33.6 \text{ mL/min}$$
$$k_f = CL_{fail}/V_D$$
$$= (33.6 \text{ mL/min} \times 1440 \text{ min/d})/313 \text{ L}$$
$$= (48.3 \text{ L/d})/313 \text{ L}$$
$$= 0.154 \text{ day}^{-1}$$

The t_{peak} is generally at 2 hours, and the k_a from the literature is about 0.76 $hour^{-1}$ or 18 day^{-1}.[15] Thus, one now has all the information needed to calculate the τ_f and dose for this patient assuming the desired C_{min} and C_{max} are 0.8 and 1.4, respectively:

$$\tau_f = [(-1/k_f)(\ln[C_{min}/C_{max}])] + t_{peak}$$
$$= [(-1/0.154)(\ln[0.8/1.4])] + 2 \text{ hours}$$
$$= [(-6.49)(-0.56)] + 2 \text{ hours}$$
$$= 3.6 \text{ days} + 2 \text{ hours}$$
$$\cong 4 \text{ days}$$
$$Dose_{po} = [(1)(1.4)(313)(18 - 0.154)]/[18(e^{-0.154(0.083)}/1 - e^{-0.154(4)}) - (e^{-18(0.083)}/1 - e^{-18(4)})]$$
$$= 0.226 \text{ mg or}$$
$$\cong \text{one 0.25 mg oral capsule every 4 days}$$

Alternatively, the predicted volume of distribution and elimination rate constant or the total-body clearance may be used to calculate a dose regimen that will maintain the desired average C_{ss} of the drug:

$$\text{Dose(mg/h)} = C_{ss}[(k_f \times V_D) \text{ or } (CL_f)]$$

Depending on how much variance above and below the average steady state one desires, the dosing interval may range from hourly to as infrequently as every 48 hours or longer. For example, if the calculated dose were 10 mg/h, the desired average steady-state concentration would be maintained with a dosing interval of 60 mg every 6 hours or 480 mg every 48 hours.

PATIENTS RECEIVING CONTINUOUS RENAL REPLACEMENT THERAPY

Continuous renal replacement therapies are used for the management of fluid overload and the removal of uremic toxins in patients with acute renal failure and other conditions.[46] The several forms of continuous renal replacement therapy in clinical use today are extensively described in Chapter 51 and several dosage regimen individualization approaches are presented and critiqued. Which of these therapies will be optimal for a given patient is dependent on several factors, including bleeding risk, degree of hypercatabolism, acid–base balance, and experience of the healthcare provider team.

PATIENTS RECEIVING CHRONIC PERITONEAL DIALYSIS

Peritoneal dialysis, like other dialysis modalities, has the potential to affect drug disposition; however, drug therapy individualization is often less complicated in these patients as a result of the limited drug clearances achieved with the variants of this procedure (see Chapter 54). In general, hemodialysis is more effective in removing drugs than peritoneal dialysis such that if a drug is not removed by hemodialysis, it is unlikely to be significantly removed by peritoneal dialysis.

Many of the factors that are important in determining drug dialyzability for other treatment modalities pertain to peritoneal dialysis as well.[48,49] Peritoneal dialysis involves the instillation of 1 to 3 L of dialysis solution into the peritoneal cavity. Waste products and other substances, including drugs, move from the blood and surrounding tissues into the dialysis solution by means of diffusion and ultrafiltration. Factors that influence drug dialyzability by peritoneal dialysis include drug-specific characteristics such as molecular weight, solubility, degree of ionization, protein binding, and volume of distribution. The intrinsic properties of the peritoneal membrane that affect drug removal include blood flow and peritoneal membrane surface area, which is approximately equal to the body surface area. There is an inverse relationship between peritoneal drug clearance and molecular weight, protein binding, and volume of distribution. Also, drug compounds that are ionized at physiologic pH will diffuse across the membrane more slowly than unionized compounds. Detailed reviews of the disposition of several drugs in chronic peritoneal dialysis patients are reported elsewhere.[47,48] Anti-infective agents are the most commonly studied drugs because of their primary role in the treatment of peritonitis[48,50] (see Chapter 54). Most other drugs can generally be dosed based on the residual renal function of the patient because the additional clearance by peritoneal dialysis is so small.

PATIENTS RECEIVING CHRONIC HEMODIALYSIS

Although many new hemodialyzers have been introduced in the past 20 years and more than 100 different ones were available in the United States in 2010, the effect of hemodialysis on drug disposition is rarely reevaluated after it is initially reported. Thus, most of the literature, especially for older medications, probably represents an underestimation of the impact of hemodialysis on its disposition.[51]

6 The impact of hemodialysis on a patient's drug therapy is dependent on several factors, including the characteristics of the drug, the dialysis conditions, and the clinical situation for which dialysis is performed. Drug-related factors that affect dialyzability include the molecular weight or size, degree of protein binding, and distribution volume.[7] The vast majority of dialysis filters in use in the United States up until the mid-1990s were composed of cellulose, cellulose acetate, or regenerated cellulose (cuprophane) (see Chapter 54), and they were generally impermeable to drugs with a molecular weight greater than 1,000 Da. Drugs that are small but highly protein bound also are not well dialyzed because both of the principal binding proteins, α_1-acid glycoprotein and albumin, have a very high molecular weight. Finally, those drugs that are widely distributed, V_D greater than 2 L/kg, are poorly removed by hemodialysis.

The hemodialysis procedure, be it acute for the management of AKI, intermittent 3 times a week or daily for an extended period or some combination thereof for the management of ESRD as well as the prescription for the patient can also dramatically affect the dialysis clearance of a medication.[52] The primary factors that vary between patients are the composition of the dialysis filter, the filter surface area, the blood and dialysate flow rates, and whether or not the dialysis unit reuses the dialysis filter. Dialysis membranes in the 21st century are predominantly composed of semisynthetic or synthetic materials (e.g., polysulfone, polymethylmethacrylate, or polyacrylonitrile). High-flux dialysis membranes have the largest pore sizes and more closely mimic the filtration characteristics of the human kidney. This allows the passage of most solutes, including drugs, that have a molecular weight of 20,000 Da or less.[53] Thus, high-molecular-weight drugs such as vancomycin are extensively cleared by this mode of dialysis. An increase in removal has also been reported with several other drugs that have lower molecular weights (Table 57–7).[51] The impact of hemodialysis on drug therapy should thus not be viewed as a generic procedure such that a certain percentage of a drug is removed with each dialysis session; neither should a "yes" answer regarding the dialyzability of drugs be considered sufficient information to make therapeutic decisions, since this provides no quantification of the impact of hemodialysis. Characteristics of the dialysis procedure that was utilized in the drug study, such as membrane composition and surface area and blood and dialysis flow rates, are thus critical data that should be

TABLE 57-7 Drug Disposition during Dialysis Depends on Dialyzer Characteristics[51]

	Hemodialysis Clearance (mL/min)[a]		Half-Life during Dialysis (h)	
Drug	**Conventional**	**High Flux**	**Conventional**	**High Flux**
Cefazolin	15.1	30–38	NR	NR
Ceftazidime	60	155[b]	3.3	1.2[b]
Cefuroxime	NR	103[c]	3.8	1.6[c]
Foscarnet	183	253[c]	NR	NR
Gentamicin	58.2	116[c]	3.0	4.3[c]
Netilmicin	46	87–109	5.0–5.2	2.9–3.4
Ranitidine	43.1	67.2[c]	5.1	2.9[c]
Vancomycin	9–21	40–150[c] 72–116[d]	35–38	4.5–11.8[c] NR

NR, not reported.
[a]Clearance in mL/min can be converted to mL/s through multiplication by 0.0167.

[c]Polysulfone filter.
[d]Polymethylmethacrylate.

known before one uses the hemodialysis clearance data to prospectively design a drug dosing regimen for a hemodialysis patient.

The quantitative impact of hemodialysis on drug disposition can be calculated in several ways.[7] The most commonly utilized means for assessing the effect of hemodialysis is to calculate the dialyzer clearance (CL_D) of the drug. The CL_D can be calculated by several approaches. The CL^b_D from blood can be calculated as $CL^b_D = Q_b[(A_b - V_b)/A_b]$, where Q_b is blood flow through the dialyzer, A_b is the concentration of drug in blood going into the dialyzer, and V_b is the blood concentration of drug leaving the dialyzer. This equation is valid only if the drug concentrations are measured in whole blood and if the drug rapidly and completely distributes into red blood cells. Because drug concentrations are generally determined in plasma, the previous equation is usually modified to $CL^p_D = Q_p[(A_p - V_p)/A_p]$ where p represents plasma and Q_p is plasma flow, which equals Q_b (1 − hematocrit). This clearance calculation most accurately reflects dialysis drug clearance as most drugs do not significantly penetrate red blood cells or bind to formed blood elements. However, one must keep in mind that venous plasma concentrations may be artificially high and CL^p_D will be low if plasma water is removed from the blood at a faster rate than drug. This tends to occur when extensive ultrafiltration is performed simultaneously with diffusion during dialysis.

The recovery clearance approach remains the benchmark for the determination of dialyzer clearance and it can be calculated as:[7]

$$CL^r_D = R/AUC_{0-t}$$

where R is the total amount of drug recovered unchanged in the dialysate and AUC_{0-t} is the area under the predialyzer plasma concentration–time curve during the period of time that the dialysate was collected. To determine the AUC_{0-t}, at least two and preferably three to four plasma concentrations should be obtained during dialysis.

The hemodialysis clearance values reported in the literature may vary significantly depending on which of these methods were used to calculate CL_D. The principal reason for this is that for most medications we do not know the degree and rapidity with which the drug crosses the red blood cell membrane. Because the CL^r_D method incorporates no assumption of the degree of red blood cell permeability, it can be reliably used as the benchmark value. The primary limitation of this calculation is that the concentrations of the drug in the dialysate may be below the sensitivity limits of the assay.

The following principles may be used to generate a drug dosage regimen recommendation for hemodialysis patients by using a value of CL_D that is reported in the literature.[7,51] Because clearance terms are additive, the total clearance during dialysis can be calculated as the sum of the patient's residual renal and nonrenal clearance during the interdialytic period (CL_{RES}) and dialyzer clearance (CL_D):

$$CL_T = CL_{RES} + CL_D$$

The half-life during the period between dialysis treatments and during dialysis can then be calculated from the following relationships using an estimate of the drug's distribution volume (V_D), which can be obtained from the literature:[14]

$$t_{1/2,offHD} = 0.693[V_D/CL_{RES}]$$
$$t_{1/2,onHD} = 0.693[V_D/(CL_{RES} + CL_D)]$$

Once the key pharmacokinetic parameters have been estimated/calculated, they may be used to simulate the plasma concentration–time profile of the drug for the individual patient and then one can ascertain how much drug to administer and when. This approach to drug therapy individualization can be accomplished in a stepwise fashion assuming first-order elimination of the drug and a one-compartment model.

For example, a 34-year-old male with ESRD was admitted to a hospital from the outpatient hemodialysis unit, where he experienced shaking and chills and had a temperature of 40°C (104°F). He weighed 70 kg (154 lb) and was 69 inches (175 cm) tall, had a residual CL_{cr} of 3 mL/min (0.05 mL/s), and received high-flux dialysis for 3 hours 3 times a week on an F80 polysulfone dialyzer. He received 140 mg of gentamicin at the end of his most recent hemodialysis treatment, which ended less than an hour prior to admission to the hospital.

The first step is to estimate this patient's pharmacokinetic parameters of gentamicin on the basis of published population data.[14] The volume of distribution in this patient is 23.1 L (0.33 L/kg × 70 kg),[54] and his residual total body clearance (CL_{RES}) estimated from the relationship between CL and creatinine clearance [$CL_{RES} = CL_{cr} \times 0.98$] is 3 mL/min (0.05 mL/s) or 0.176 L/h. The elimination rate constant can be approximated as:

$$k = CL_{RES} \div V_D$$
$$= 0.176 \text{ L/h} \div 23.1 \text{ L}$$
$$= 0.0076 \text{ hr}^{-1}$$

The hemodialysis clearance of gentamicin is dependent on the dialyzer and a value of 116 mL/min is a reasonable estimate for this dialyzer.[51]

One now can predict what the plasma concentrations of gentamicin will be over the next 24 to 48 hours, assuming the infusion time for the drug (t') was 30 minutes. The concentration at the end of the 30-minute infusion (C_{max}) would be:

$$C_{max} = \frac{(\text{Dose}/t')(1 - e^{-kt'})}{CL_{RES}}$$

$$C_{max} = \frac{(280 \text{ mg/h})(1 - e^{-(0.0076)0.5})}{0.176 \text{ L/h}}$$

$$C_{max} = (1{,}944 \text{ mg/L})(0.003) = 6.0 \text{ mg/L}$$

The plasma concentration prior to the next dialysis session (C_{bD}), which is 44 hours away, and the concentration four hours later after dialysis (C_{aD}) can be calculated as:

$$C_{bD} = C_{max} \times e^{-(CL_{RES}/V_D) \times t}$$
$$= 6.0 \times e^{-0.0076 \times 44}$$
$$= 4.3 \text{ mg/L}$$
$$C_{aD} = C_{bD} \times e^{-((CL_{RES} + CL_D)/V_D) \times t}$$
$$= 4.3 \times e^{-((0.176 + 6.96)/23.1) \times 4}$$
$$= 4.3 \times e^{-0.309 \times 4}$$
$$= 1.25 \text{ mg/L}$$

On the basis of these data, a second dose will likely be required at the end of the next dialysis session as one generally desires to have gentamicin concentrations fall below 2 mg/L (2 mcg/mL; 4.2 mmol/L) before administering another dose.

During this interdialytic interval, several blood samples were collected to characterize this patient's residual gentamicin clearance, distribution volume, and the clearance of gentamicin during dialysis. Blood samples were therefore collected at the following times after the first dose:

DAY 1:	7 PM (2 hours after dose)	6.5 mg/L or mcg/mL (13.6 mmol/L)
DAY 2:	8 AM (39 hours after dose; just before dialysis)	4.1 mg/L or mcg/mL (8.6 mmol/L)
DAY 3:	12 noon (immediately after dialysis)	2.0 mg/L or mcg/mL (4.2 mmol/L)

The C_{max} can be calculated by back-extrapolation to the end of the infusion as described in Chapter 8. The elimination rate during the interdialytic period (k_{ID}) and during dialysis (k_{DD}), and the V_D can be calculated as:

$$k_{ID} = (\ln C_1/C_2)/\Delta t$$
$$k_{ID} = (\ln 6.5/4.1)/37 = 0.0125/\text{h}$$
$$V_D = \frac{Dose/t'}{k_{ID}} \frac{1 - e^{-k_{ID}t'}}{(C_{max} - C_{min}e^{-k_{ID}t'})}$$
$$V_D = \frac{140/0.5}{0.0125} \frac{1 - e^{-(0.0125)0.5}}{(6.7 - 0.0e^{-(0.0125)0.5})}$$
$$V_D = \frac{134.4}{6.7} = 20 \text{ L}$$
$$k_{DD} = (\ln C_2/C_3)/\Delta t$$
$$k_{DD} = (\ln 4.1/2.0)/4 = 0.179/\text{h}$$

where Δt is the time in hours between the two measured concentrations and C_{min} the gentamicin concentration in plasma prior to the administration of the first dose is zero.

The patient's residual clearance (CL_{RES}) of gentamicin can then be calculated as:

$$CL_{RES} = V_D \times k_{ID}$$
$$CL_{RES} = 20.0 \text{ L} \times 0.0125 = 0.25 \text{ L/h or } 4.2 \text{ mL/min}$$

The dialyzer clearance (CL_D) can be calculated as follows because one knows the total clearance during dialysis (CL_T) and CL_{RES}:

$$CL_D = CL_T - CL_{RES}$$
$$CL_D = (k_{DD} \times V_D) - 4.2 \text{ mL/min}$$
$$CL_D = (0.179/\text{h} \times 20.0 \text{ L}) - 4.2 \text{ mL/min}$$
$$CL_D = (3.6 \text{ L/h or } 59.6 \text{ mL/min}) - 4 .2 \text{ mL/min}$$
$$CL_D = 55.4 \text{ mL/min}$$

The ultimate reason for measuring the plasma concentrations of aminoglycosides and several other agents is to individualize the patient's dosage regimen to achieve a bacteriologic cure while preserving residual renal function. Thus there remains one important step in our evaluation: the calculation of the dose this patient should receive next. The two factors that enter into this decision are the desired peak and trough concentrations and the degree of rebound in drug concentrations, after the end of dialysis. Because gentamicin concentrations have been noted to increase by approximately 25% within 1.5 to 2 hours after the end of hemodialysis, the trough concentration of this patient can be considered to be 2.5 mg/L (2.0 mg/L × 1.25). Although this value is higher than one might like to maintain in an individual with normal renal function, a prolonged period of almost 24 hours would be required just to have the concentration drop below 2.0 mg/L (2.0 mcg/mL; 4.2 mmol/L). Assuming the desired peak concentration was 7.0 mg/L (7.0 mcg/mL; 14.6 mmol/L), the postdialysis dose this patient would need can then be calculated using the simplified approach below, because the elimination half-life is extremely prolonged relative to the infusion time, and thus minimal drug is eliminated during the infusion period:

$$\text{Dose} = V_D \times (C_{max} - C_{min})$$
$$= 20.0 \text{ L} \times (7.0 - 2.5) = 90 \text{ mg}$$

7 It is common practice in most hemodialysis units to administer drugs after the patient has received dialysis on the premise that it is desirable to minimize the loss of drug that would result from the additional clearance during hemodialysis. Certainly, administration of antihypertensive agents and vasoactive drugs should be avoided in the hours prior to a hemodialysis session to minimize the likelihood of hypotension. However, emerging pharmacokinetic and pharmacodynamic considerations suggest that this may not be the optimal approach for several other agents, such as aminoglycosides[55–57] and vancomycin.[58–60] Two evaluations of predialysis and one of intradialytic dosing of aminoglycosides indicate that similar peak concentrations, a prime indicator of efficacy, can be obtained in these scenarios relative to those observed with postdialysis dosing.[55–56] The area under the concentration-time curve during the dosing interval and the subsequent predialysis concentrations were noted to be significantly reduced and thus the risk of ototoxicity and further renal injury may be minimized. The best dosing schedule, a dose roughly twice that traditionally employed for postdialysis administration, in the 26 patients evaluated by Teigen et al., resulted in the achievement of the desired peak and area under the concentration–time curve in approximately 90% of patients.[56] The administration of traditional doses of tobramycin (1.5 mg/kg) or vancomycin (1,000 mg) during dialysis has been associated with markedly lower areas under the concentration–time curve than those observed when the same dose was administered postdialysis; consequently, higher dosage regimens are usually necessary to compensate for the additional loss of drug during the dialysis procedure. It is highly recommended that aminoglycoside and vancomycin concentrations in hemodialysis patients be measured after the first dose and dialysis session and so that the dosage regimen can be individualized accordingly using Bayesian methodology whenever possible.

CONCLUSIONS

Subtherapeutic or supratherapeutic responses to drugs in patients with renal insufficiency are often misinterpreted and not recognized as such. The adverse outcomes associated with inappropriate drug dosing have not been quantified but do warrant future investigations. Sound pharmacokinetic principles, used in concert with reliable population pharmacokinetic estimates, should ultimately yield the optimal approach to drug dosage regimen design for patients with renal insufficiency. Individualization of therapy should be undertaken whenever clinical therapeutic monitoring tools are available. The key action step is to use the knowledge we have to improve patient outcomes. The recent study of van Dijk et al. is an unfortunate reminder of how far we still have to go.[61] They observed that although dosage adjustments based on renal function were warranted in 24% of the prescriptions of the patients with CL_{cr} less than 51 mL/min (0.85 mL/s), such adjustments were only performed in 59% of cases.

ABBREVIATIONS

A_b: concentration of drug in blood going into the dialyzer (arterial side)

A_p: concentration of drug in plasma going into the dialyzer (arterial side)

$AUC_{0\text{-}t}$: the area under the predialyzer plasma concentration–time curve during hemodialysis

C_a: concentration of the drug in the plasma going into a filter

C_{aD}: plasma concentration after dialysis

C_{ave}: average plasma concentration

C_{bD}: plasma concentration prior to the next dialysis session

C_{df}: concentration of drug in the dialysis fluid

C_{ss}: average steady-state plasma concentration

CL: total-body clearance

CL^{b}_{D}: dialyzer clearance from blood

CL_{cr}: creatinine clearance

CL_{D}: dialyzer clearance

CL_{fail}: clearance of a drug in patients with impaired renal function

CL_{norm}: clearance of a drug in patients with normal renal function

CL^{p}_{D}: dialyzer clearance from plasma

CL_{PT}: estimated total body clearance for a given patient

CL_{R}: net renal excretion

$CL_{reabsorption}$: tubular reabsorption

CL_{RES}: residual drug clearance in a dialysis patient

$CL_{secretion}$: tubular secretion

C_{max}: peak drug concentration

CNS: central nervous system

C^{t}_{p}: desired plasma concentration at time t

CYP: cytochrome P450 enzymes

D_{f}: maintenance dose for a patient with renal insufficiency

D_{n}: dose for a patient with normal renal function

ESRD: end-stage renal disease

f_{e}: fraction of drug eliminated unchanged in the urine

f_{u}: fraction of drug unbound to plasma proteins

GFR: glomerular filtration rate

IC_{50}: inhibitory concentration of 50%

k_{a}: absorption rate constant

k: elimination rate constant

k_{DD}: elimination rate constant during dialysis

k_{f}: ratio of the patient's creatinine clearance to the assumed normal value of 120 mL/min

k_{ID}: elimination rate constant between dialysis sessions (interdialytic)

Q: kinetic parameter/dosage-adjustment factor

Q_{b}: blood flow through the dialyzer

Q_{p}: plasma flow through the dialyzer = Q_{b} (1-hct)

R: the total amount of drug recovered unchanged in the dialysate

τ_{f}: dosing interval in a patient with renal failure

τ_{p}: practical dosing interval for a patient with renal failure

τ_{n}: dosing interval in a patient with normal renal function

t_{max}: time-to-peak drug concentration

$t_{1/2}$: half-life

$t_{1/2,onHD}$: half-life during dialysis

$t_{1/2,offHD}$: half-life off dialysis

V_{area}: volume of distribution area

V_{β}: volume of distribution

V_{c}: volume of the central compartment

V_{D}: volume of distribution

V_{ss}: volume of distribution at steady state

CHAPTER 58

Disorders of Sodium and Water Homeostasis

JAMES D. COYLE AND GARY R. MATZKE

KEY CONCEPTS

1. Hypovolemic hypotonic hyponatremia is relatively common in patients taking thiazide diuretics. Thiazide-induced hyponatremia is usually mild and relatively asymptomatic. Hyponatremia rarely if ever occurs with loop diuretics.
2. The syndrome of inappropriate secretion of antidiuretic hormone causes euvolemic hypotonic hyponatremia. Common causes of this syndrome include lung cancer, central nervous system disorders, pulmonary disorders, and a variety of drugs.
3. Symptoms of hyponatremia are usually neurologic in nature and symptom severity depends both on the magnitude of the decrease in serum sodium concentration and the rate at which it developed. Treatment of hyponatremia is associated with a risk of osmotic demyelination syndrome, a severe neurologic complication that can develop if the rate of serum sodium correction exceeds 8 to 12 mEq/L (8–12 mmol/L) within 24 hours.
4. Asymptomatic or mildly symptomatic hyponatremic patients should generally be managed conservatively with treatment directed at the underlying cause. A 0.9% sodium chloride infusion can be cautiously used to correct the serum sodium in patients with hypovolemic hypotonic hyponatremia and moderate to severe symptoms. A 3% sodium chloride infusion can be cautiously used in patients with euvolemic or hypervolemic hypotonic hyponatremia and moderate to severe symptoms.
5. Hypernatremia most commonly occurs when increased water or hypotonic fluid losses are not offset by increased water intake or administration. For example, patients with diabetes insipidus excrete large volumes of dilute urine, but usually develop hypernatremia only if their water intake does not increase to offset the increased water losses.
6. Symptoms of hypernatremia are usually neurologic in nature, and range in severity from weakness, lethargy, restlessness, irritability, and confusion to twitching, seizures, coma, and death. The severity of symptoms depends on both the magnitude of the increase in serum sodium and the rate at which it developed.
7. The treatment goals in patients with hypernatremia include cautious correction of the serum sodium concentration and, when appropriate, restoration of a normal extracellular fluid volume. Too rapid correction of the serum sodium can result in cerebral edema, seizures, neurologic damage, and possibly death. To minimize the risk of these complications, the serum sodium concentration should be corrected at a maximum rate of 0.5 to 1 mEq/L (0.5–1 mmol/L) per hour, depending on the rate of hypernatremia development, and be limited to no more than 10 mEq/L (10 mmol/L) per day.
8. Patients with central diabetes insipidus should be treated with intranasal desmopressin acetate, with goals of decreasing urine volume to less than 2 L per day while maintaining the serum sodium concentration between 137 and 142 mEq/L (137 and 142 mmol/L). Patients with nephrogenic diabetes insipidus should be treated by correcting the underlying cause when possible, and sodium chloride restriction in conjunction with a thiazide diuretic to decrease the extracellular fluid volume by approximately 1 to 1.5 L.
9. Edema can develop as a primary defect in renal sodium handling or as a response to a decreased effective circulating volume. It is usually first detected in the feet or pretibial areas of ambulatory patients. Pulmonary edema, evidenced by auscultatory crackles, can be life-threatening.
10. Diuretics are the primary pharmacologic means for achieving the desired therapeutic outcomes of minimization of edema and improving organ function. Diuretic resistance can be overcome by using an increased dose or by using a combination of a loop diuretic and a thiazide or thiazide-like diuretic.

The human body tightly regulates blood volume and plasma osmolality as both are essential for normal cellular function. Blood volume is important because it is a determinant of effective tissue perfusion which is required to deliver oxygen and nutrients to and remove metabolic waste products from tissues. Plasma osmolality is an important determinant of intracellular volume. Maintenance of normal intracellular volume is particularly critical in the brain, where alterations can result in significant neural dysfunction and potentially death.

The homeostatic mechanisms for regulating blood volume and plasma osmolality involve control of sodium and water balance.[1] Interestingly, the homeostatic mechanisms for controlling blood volume are focused on controlling sodium balance. In contrast, the homeostatic mechanisms for controlling plasma osmolality, which is largely determined by serum sodium concentration, are focused on controlling water balance. Thus, sodium and water balance are closely related and are frequently considered together. Disorders of sodium and water homeostasis are common and potentially serious.

It is important for clinicians to understand these disorders because they can both be caused by and treated with medications. This chapter reviews the etiology, classification, clinical presentation, and therapy for disorders of sodium and water homeostasis.

SODIUM AND WATER HOMEOSTASIS

Hypo- and hypernatremia are syndromes of altered plasma tonicity and cell volume that reflect a change in the ratio of total exchangeable body sodium to total body water. Many factors affect tonicity and water balance and a sound understanding of the pathogenesis and evaluation approaches are of utmost importance if one is to successfully prevent and manage these syndromes.

Sixty percent of total body water is located intracellularly, whereas 40% is contained in the extracellular space.[1] Sodium and its accompanying anions, chloride and bicarbonate, comprise more than 90% of the total osmolality of the extracellular fluid (ECF), whereas intracellular osmolality is primarily dependent on the concentration of potassium and its accompanying anions (mostly organic and inorganic phosphates). The differential concentrations of sodium and potassium in the intra- and extracellular fluid are maintained by the sodium-potassium-adenosine triphosphatase (Na^+-K^+-ATPase) pump.[1,2] Most cell membranes are freely permeable to water, and thus the osmolality of intra- and extracellular body fluids is the same.

Solutes that cannot freely cross cell membranes, such as sodium, are referred to as effective osmoles. The concentration of effective osmoles in the ECF determines the tonicity of the ECF, which directly affects the distribution of water between the extra- and intracellular compartments.[1] Addition of an isotonic solution to the ECF will result in no change in intracellular volume because there will be no change in the effective osmolality of the ECF. Addition of a hypertonic solution to the ECF, however, will result in a decrease in cell volume, whereas addition of a hypotonic solution to the ECF will result in an increase in cell volume. Table 58–1 summarizes the composition of commonly used intravenous solutions and their respective distribution into extracellular and intracellular compartments following infusion.

The serum sodium concentration is tightly regulated, and usually varies by no more than 2% to 3%. Regulation of serum sodium concentration occurs indirectly via mechanisms that control its determinants, plasma osmolality, and blood volume.[1] The kidney regulates water excretion through a feedback mechanism with the hypothalamus, such that the serum osmolality remains relatively constant (275–290 mOsm/kg [275–290 mmol/kg]) despite day-to-day variations in water intake. Plasma osmolality is largely determined by the concentrations of sodium and the accompanying anions chloride and bicarbonate, and can be estimated as:

$$Sosm = (2 \times S_{Na}) + (B_{glucose}/18) + (BUN/2.8)$$

where Sosm = serum osmolality in milliosmoles per kilogram; S_{Na} = serum sodium concentration in mEq/L; $B_{glucose}$ = glucose concentration in mg/dL; and BUN = blood urea nitrogen concentration in mg/dL.[1,3]

Alternatively, when using SI units the equation becomes:

$$Sosm = (2 \times S_{Na}) + (B_{glucose}) + (BUN)$$

where Sosm = serum osmolality in millimoles per kilogram; S_{Na} = serum sodium concentration in mmol/L; $B_{glucose}$ = glucose concentration in mmol/L; and BUN = blood urea nitrogen concentration in mmol/L.[1,3]

Arginine vasopressin (AVP), commonly known as antidiuretic hormone (ADH), is released from the posterior pituitary when the plasma osmolality increases by 1% to 2% or more.[1] AVP binds to the vasopressin 2 (V2) receptors on the basolateral surface of renal tubular epithelial cells, resulting in the insertion of water channels (aquaporin 2) into the apical tubular lumen surface of the cell.[4] Water can then pass through the cell into the peritubular capillary space where it is then reabsorbed into the systemic circulation. An increase in serum osmolality sensed in the hypothalamus results not only in AVP release, but also in stimulation of thirst. The combination of an increase in water intake and a decrease in water excretion results in a decrease in the serum osmolality and inhibition of AVP secretion once the plasma osmolality is restored to normal.

Nonosmotic release of AVP occurs when a decrease in a person's effective circulating blood volume results in a decrease in systemic blood pressure.[1] The effective circulating volume is that part of the ECF that is located in the arterial system and is responsible for organ perfusion.[1] A decrease in the effective circulating volume (more accurately, the pressure associated with that volume) activates arterial baroreceptors in the carotid sinus and glomerular afferent arterioles, resulting in stimulation of the renin-angiotensin system and increased synthesis of angiotensin II. Angiotensin II stimulates both nonosmotic release of AVP and thirst. This volume stimulus overrides osmotic inhibition of AVP release, and conservation of water fosters restoration of effective circulating volume and blood pressure at the expense of hypo-osmolality.

Proper assessment of a patient with an abnormal serum sodium concentration requires knowledge of the fact that changes in the serum sodium concentration do not necessarily correlate with changes in ECF volume or sodium content as the sodium concentration is determined by the ratio of the ECF sodium content and ECF volume.[1] Although hyponatremia and hypernatremia can be associated with conditions of high, low, or normal ECF sodium and volume, both conditions are most commonly the result of abnormalities of water metabolism.[1]

HYPONATREMIA

EPIDEMIOLOGY AND ETIOLOGY

Hyponatremia (serum sodium <135 mEq/L [<135 mmol/L]) is the most common electrolyte abnormality encountered in clinical

TABLE 58-1 Composition of Intravenous Replacement Solutions

Solution	Dextrose	[Na^+] (mEq/L or mmol/L)	[Cl^-] (mEq/L or mmol/L)	Tonicity	Distribution		Free Water/L
					% ECF	% ICF	
D_5W	5 g/dL (50 g/L)	0	0	Hypotonic	40	60	1,000 mL
0.45% sodium chloride	0	77	77	Hypotonic	73	37	500 mL
0.9% sodium chloride	0	154	154	Isotonic	100	0	0 mL
3% sodium chloride[a]	0	513	513	Hypertonic	100	0	–2,331 mL

Cl^-, chloride; D_5W, 5% dextrose in water; ECF, extracellular fluid; ICF, intracellular fluid; Na^+, sodium.
[a]This solution will result in osmotic removal of water from the intracellular space.

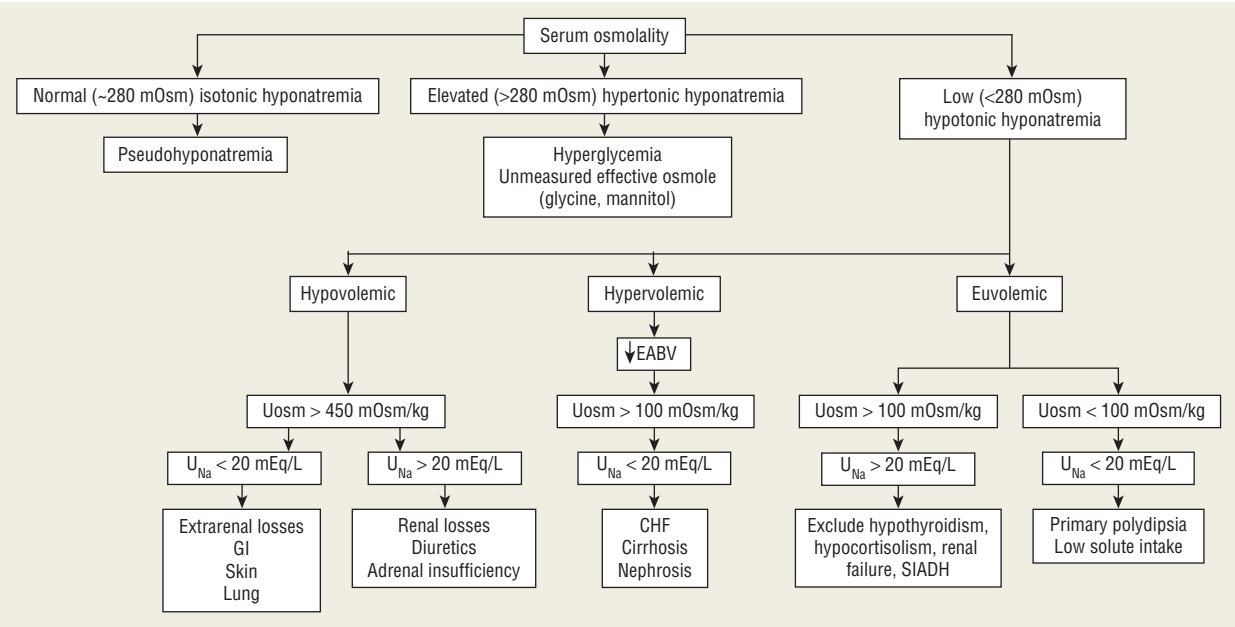

FIGURE 58-1. Diagnostic algorithm for the evaluation of hyponatremia. (CHF, congestive heart failure; SIADH, syndrome of inappropriate secretion of antidiuretic hormone; U_{Na}, urine sodium concentration [values in mEq/L are numerically equivalent to mmol/L]; Uosm, urine osmolality [values in mOsm/kg are numerically equivalent to mmol/kg].)

practice.[5,6] Although its prevalence is not well established and varies with the patient population studied, it has been estimated to be as high as 28% in patients admitted to an acute care hospital. Mild hyponatremia (serum sodium <136 mEq/L [<136 mmol/L]) was observed in 42.6%, while 6.2% of patients had values <126 mEq/L (<126 mmol/L), and only 1.2% had values <116 mEq/L (<116 mmol/L). The incidence has been reported to be as high as 21% in patients seen in ambulatory hospital clinics, and 7% in community clinics.[7] Drug-induced hyponatremia, especially that associated with diuretics and psychotropic medications, is more commonly seen in women than men. Increasing age (>30 years) is also clearly a risk factor for hyponatremia, independent of gender.[7]

Hyponatremia incidence in the nursing home setting is 2-fold higher than that observed in similar aged-community dwelling individuals.[5] Over 75% of these episodes were precipitated by increased fluid intake of hypotonic oral or intravenous fluids. Similarly, the ingestion of excessive quantities of fluids has been identified as a key risk factor in marathon runners who develop hyponatremia. Although women had a 3-fold higher rate of hyponatremia, smaller body size and longer racing time, not gender, appear to be the principle factors which account for the increased incidence.[8]

Recognition of the high prevalence of hyponatremia is important because this condition is associated with significant morbidity and mortality.[9,10,11] Transient or permanent brain dysfunction can result from either the acute effects of hypo-osmolality or from too rapid correction of hypo-osmolality in patients with symptomatic hyponatremia. Hyponatremia is predominantly the result of an excess of extracellular water relative to sodium because of impaired water excretion. The kidney normally has the capacity to excrete large volumes of dilute urine after ingestion of a water load. Nonosmotic release of AVP, however, can lead to retention of water and to a drop in serum sodium concentration, despite a fall in both serum and intracellular osmolality. The causes of nonosmotic release of AVP include hypovolemia, decreased effective circulating volume as seen in patients with chronic heart failure (CHF), nephrosis, and cirrhosis. The syndrome of inappropriate antidiuretic hormone secretion (SIADH) is also a common cause of hyponatremia which is associated with oncologic disease, especially small cell lung cancer.[10] The pathophysiology, clinical features, and management of hyponatremia are detailed below.

PATHOPHYSIOLOGY

Hyponatremia can be associated with normal, increased, or decreased plasma osmolality, depending on its cause (Fig. 58-1).[1,3] Hyponatremia in patients with normal serum osmolality can be caused by hyperlipidemia or hyperproteinemia. Historically, this form of hyponatremia, termed *pseudohyponatremia*, was an artifact of the method of serum sodium concentration measurement. This laboratory artifact is uncommon today and has been overcome with the use of ion-specific electrodes to measure the serum sodium concentration. If the sodium concentration in a laboratory is still measured by flame photometry, the volume of serum will be overestimated because the elevated lipids or proteins account for a greater proportion of the total volume of the sample (Fig. 58–2). Because the sodium is distributed in only the water component of serum, the measured serum sodium concentration is falsely decreased. The

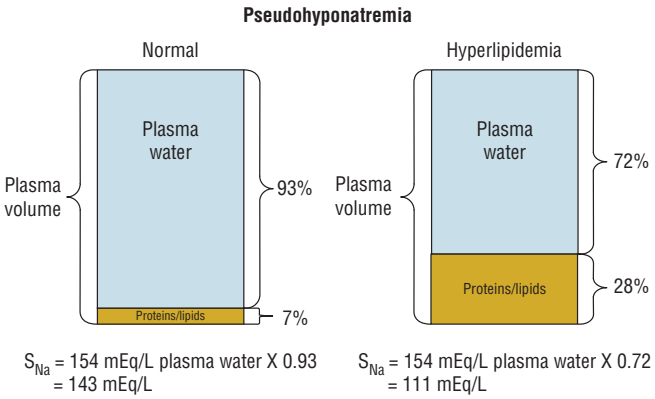

FIGURE 58-2. Elevated lipids or proteins result in a larger discrepancy between the volume of the sample and plasma water, leading to a falsely low measurement of the serum sodium concentration when using the method of flame photometry. (S_{Na}, serum sodium concentration [values in mEq/L are numerically equivalent to mmol/L].)

measurement of serum osmolality, however, is not significantly affected, leading to a discrepancy between the calculated and measured serum osmolality.

Hyponatremia associated with increased serum osmolality, termed *hypertonic hyponatremia*, suggests the presence of excess, nonsodium-effective osmoles in the ECF.[1,3] This is most frequently encountered in patients with hyperglycemia. Elevated concentrations of glucose provide effective plasma osmoles, resulting in diffusion of water from the cells into the extracellular compartment thereby expanding the ECF, which results in decrease in the serum sodium concentration. For every 100 mg/dL (5.6 mmol/L) increase in the serum glucose concentration, the serum sodium level decreases by 1.7 mEq/L (1.7 mmol/L), and the serum osmolality increases by 2 mOsm/kg (2 mmol/kg).[3] It should be noted that this correction is only a rough estimate because the increase in serum sodium varies substantially with the degree of hyperglycemia.[12] Other substances such as mannitol, glycine, and sorbitol that do not cross cellular membranes provide effective osmoles and can also cause hypertonic hyponatremia. The presence of these unmeasured osmoles should be suspected in patients with hypertonic hyponatremia if there is a significant osmolal gap, that is the difference between the measured and calculated plasma osmolality.[1]

Hyponatremia associated with decreased plasma osmolality, termed *hypotonic hyponatremia*, is the most common form of hyponatremia and has many potential causes (see Fig. 58–1).[1,3] An important step in the diagnostic evaluation of patients with hypotonic hyponatremia is clinical assessment of the patient's extracellular fluid volume.[3] Categorization of these patients into one of three groups (decreased, increased, or clinically normal ECF volume) is very helpful in identifying the pathophysiologic mechanisms responsible for the hyponatremia and an appropriate treatment regimen.

Hypovolemic Hypotonic Hyponatremia

Most patients with ECF volume contraction lose fluids that are hypotonic relative to plasma and thus can be transiently hypernatremic. This includes patients with fluid losses caused by diarrhea, excessive sweating, and diuretics. This transient hypernatremic hyperosmolality results in osmotic release of AVP and stimulation of thirst. If sodium and water losses continue, more AVP is released as a result of hypovolemia. Patients who then drink water or who are given hypotonic fluids intravenously retain water and develop hyponatremia. These patients typically have a urine osmolality greater than 450 mOsm/kg (greater than 450 mmol/kg), reflecting the presence of AVP and formation of a concentrated urine.[13] The urine sodium concentration is <20 mEq/L (<20 mmol/L) when sodium losses are extrarenal, as in patients with diarrhea, and >20 mEq/L (>20 mmol/L) in patients with renal sodium losses, as occurs in the setting of diuretic use or adrenal insufficiency.[13]

1 Hypotonic hyponatremia is relatively common in patients taking thiazide diuretics.[14] Thiazide-induced hyponatremia is usually mild, but can occasionally be severe and symptomatic.[15] It typically develops within 2 weeks of the initiation of therapy, but can occur late in therapy, particularly if there has been a recent increase in the diuretic dose or other causes of hyponatremia develop.[1,15]

The mechanism of thiazide-induced hyponatremia is likely related to the balance of its direct and indirect effects.[1] Thiazides exert their diuretic effect by blocking sodium reabsorption in the distal tubules of the renal cortex, thereby increasing sodium and water removal from the body. The resulting decrease in effective circulating volume stimulates AVP release. Increased AVP release results in increased reabsorption of free water in the collecting duct, as well as increased water intake because of stimulation of thirst. Hyponatremia develops when the net result of these effects is the loss of more sodium than water.

Interestingly, hyponatremia occurs infrequently with loop diuretics.[1] This difference between thiazide and loop diuretics likely relates to their different sites of action. Loop diuretics exert their diuretic effect by blocking sodium reabsorption in the ascending limbs of the loop of Henle, many of which are located in the renal medulla. This action decreases medullary osmolality. Thus, when the loop diuretics decrease effective circulating volume and stimulate AVP release, less water reabsorption occurs in the collecting ducts than would occur if the osmolality of the renal medulla were normal. Thiazide diuretics do not alter medullary osmolality as their site of action is located in the renal cortex rather than in the medulla. In addition, most loop diuretics have a shorter half-life than the thiazides, and patients can therefore replete the urinary sodium and water losses prior to taking the next dose, thereby minimizing AVP stimulation.

Euvolemic Hypotonic Hyponatremia

2 Euvolemic hypotonic hyponatremia is associated with a normal or slightly decreased ECF sodium content and increased total body water and ECF volume. The increase in ECF volume is usually not sufficient to cause peripheral or pulmonary edema, and thus patients appear clinically euvolemic. Euvolemic hyponatremia is most commonly the result of SIADH release. In this syndrome, water intake exceeds the capacity of the kidneys to excrete water, either because of an increased release of AVP via nonosmotic and/or nonphysiologic processes or enhanced renal sensitivity to AVP.[16] The urine osmolality in patients with SIADH is generally greater than 100 mOsm/kg (greater than 100 mmol/kg), and the urine sodium concentration is usually greater than 20 mEq/L (greater than 20 mmol/L) as a result of the ECF volume expansion.

The most common causes of SIADH include tumors such as small cell lung cancer, central nervous system disorders (e.g., head trauma, stroke, meningitis, and pituitary surgery), as well as pulmonary disease.[3] Patients with renal insufficiency, adrenal insufficiency, and hypothyroidism can also present with euvolemic hyponatremia, and the evaluation of patients with suspected SIADH should always include consideration of these disorders. A wide variety of drugs can also cause SIADH by enhancing AVP release, the renal effect of AVP or by unknown mechanisms.[3,10,11,17,18] (Table 58–1) The differential diagnosis of euvolemic hypotonic hyponatremia also includes primary or psychogenic polydipsia. Patients with this disorder drink more water (usually >20 L/day) than the kidneys can excrete as solute-free water. Unlike SIADH, however, AVP is suppressed, resulting in a urine osmolality that is less than 100 mOsm/kg (less than 100 mmol/kg). The urine sodium is typically low (<15 mEq/L [<15 mmol/L]) as a result of urinary dilution.[19] Hyponatremia can develop with more modest water intake in patients who are ingesting a very low-solute diet, such as a low-sodium vegetarian diet.

Hypervolemic Hypotonic Hyponatremia

Hyponatremia associated with an increase in ECF volume occurs in conditions in which renal sodium and water excretion are impaired. Patients with cirrhosis, congestive heart failure, and nephrotic syndrome have an expanded ECF volume and edema, but a decreased effective circulating volume. This decreased volume results in renal sodium retention, and eventually ECF volume expansion and edema. At the same time, there is nonosmotic release of AVP and retention of water in excess of sodium, which perpetuats the hyponatremia.

CLINICAL PRESENTATION

3 Patients with chronic, mild hyponatremia (serum sodium concentration greater than 125–130 mEq/L [greater than

125–130 mmol/L]) are usually asymptomatic, with hyponatremia being discovered incidentally when serum electrolytes are measured for other purposes.[1,3,20] However, recent data from a small number of carefully evaluated patients suggest that it might be more accurate to say that symptoms of mild hyponatremia are frequently unnoticed by both physician and patient.[21] These data suggest that chronic, mild hyponatremia is associated with impairment of attention, posture, and gait, all of which contribute to a substantially increased risk of falls. Even those who seem to be "asymptomatic" when formally tested can be shown to have impaired attention and gait to a degree that is compatible with a blood alcohol level of 0.06% (13 mmol/L).[22,23]

Patients with moderate (serum sodium concentration of 115–125 mEq/L [115–125 mmol/L]) to severe (serum sodium concentration less than 110–115 mEq/L [110–115 mmol/L]) or rapidly developing hypotonic hyponatremia often present with a range of neurologic symptoms resulting from hypoosmolality-induced volume expansion of brain cells.[1,3,20] Classic symptoms include nausea and malaise, headache, lethargy, restlessness, and disorientation, and in some seizures, coma, permanent brain damage, respiratory arrest, brainstem herniation, and death.

The presence of these symptoms and their severity depend on both the magnitude of the hyponatremia and the rate at which the hyponatremia developed.[1,3,20] The magnitude of the hyponatremia is important because serum osmolality decreases in direct proportion to the serum sodium concentration, and water movement into brain cells increases as serum osmolality decreases. The rate of osmolality change is an important factor because brain cells are able to adjust their intracellular osmolality to minimize cellular volume changes in response to volume changes, but time is required for this adaptation to occur.[1,24] When a decline in plasma osmolality causes movement of water into brain cells, sodium, potassium, and *organic osmolytes* move out of the cells to decrease intracellular osmolality and minimize intracellular water movement. Organic osmolytes, such as myoinositol, are osmotically active substances that contribute substantially to controlling intracellular osmolality without directly altering cellular function.[24] The various components of this adaptive mechanism occur over different time frames, with sodium and potassium efflux occurring over minutes to several hours and organic osmolyte efflux occurring over hours to days.[24] Maximal compensation for a decrease in plasma osmolality typically requires up to 48 hours. Thus, acute changes in plasma osmolality are not compensated for instantaneously and are more likely to be associated with symptoms. Patients with concurrent respiratory failure and hypoxemia are at greater risk for adverse neurologic outcomes because hypoxemia diminishes the capacity of the brain to actively transport solute out of cells, leading to a higher incidence of cerebral edema.[25] Children and women have been noted to have poor clinical outcomes relative to adults and males. For example, women have a 25-fold higher risk of death or permanent neurological damage than men.[26]

In addition to neurologic symptoms, patients with hypovolemic hyponatremia can present with signs and symptoms of hypovolemia, including dry mucous membranes, decreased skin turgor, tachycardia, decreased jugular venous pressure, and orthostatic hypotension. These findings are helpful in identifying the type of hyponatremia.

The brain's adaptation to changes in plasma osmolality is also associated with symptoms that can develop if hyponatremia is corrected too rapidly (i.e., >12 mEq/L [>12 mmol/L] per day). These patients might experience an acute decrease in brain cell volume, which contributes to the pathogenesis of *osmotic demyelination syndrome*.[27,28] Patients with this complication might develop para- or quadriparesis, pseudo-bulbar palsy, and locked-in syndrome 5 to 7 days after treatment because of demyelination lesions in the pons.[28,29] Patients who have a significant degree of cerebral adaptation to hypotonic hyponatremia are at higher risk of experiencing this syndrome.[28] This is presumably because these patients have lower intracellular osmolalities at the initiation of therapy, which results in greater decreases in intracellular volume when the plasma osmolality is raised rapidly. Brain adaptation to increases in plasma osmolality requires time, just as was true for its initial adaptation to a decrease in serum sodium concentration.

CLINICAL PRESENTATION OF HYPONATREMIA

General

- Hyponatremia is asymptomatic in most patients. Symptoms directly attributable to hyponatremia include neurologic dysfunction associated with cerebral edema.

Symptoms

- The presence and severity of symptoms are related both to the magnitude and rapidity of onset of the hyponatremia. Nausea and malaise are the earliest findings, followed by headache, lethargy, restlessness, and disorientation, and eventually seizures, coma, permanent brain damage, respiratory arrest, brainstem herniation, and death if hyponatremia is severe or develops rapidly. Other symptoms that can be seen with hyponatremia are those attributable to its underlying cause, such as volume depletion in patients with hypovolemic hypotonic hypo-osmolality or volume excess in patients with hypervolemic hypotonic hyponatremia.

Signs

- General: Dry mucous membranes, decreased skin turgor, tachycardia, decreased jugular venous pressure, and postural hypotension can be present in hypovolemic patients.
- Pulmonary: Noncardiogenic pulmonary edema has been described.
- Neurologic: Depressed reflexes. Rapid correction of hyponatremia can result in an acute decrease in brain cell volume resulting in demyelinating brain injury.

Laboratory Tests

- Serum sodium values <135 mEq/L (<135 mmol/L) are present. Plasma osmolality and urine sodium concentration can be helpful in diagnosing the cause. Tests including but not limited to serum glucose and lipids and tests to assess kidney and thyroid function should be conducted to identify or rule out potential causes.

TREATMENT

Hyponatremia

DESIRED OUTCOME

4 The goal of treating patients with hypovolemic hypotonic hyponatremia is to resolve the underlying cause of the sodium and ECF volume deficits, and safely correct the hyponatremia. The treatment goals for hypervolemic and euvolemic hypotonic patients depend on the underlying cause of the hyponatremia and the severity of the patient's symptoms. Patients with an acute onset of hyponatremia or severe symptoms require more aggressive therapy to correct the hypotonicity. The initial goal for these patients is to increase plasma tonicity enough to control the severe symptoms; this typically requires a relatively small increase in serum sodium concentration

of approximatley 5%.[3] Once control of the severe symptoms is achieved, full correction of the serum sodium concentration should be achieved at a controlled rate. Asymptomatic patients and patients with mild to moderate symptoms do not require rapid correction of the serum sodium and the treatment is dictated by the underlying etiology. In all cases the goal is to avoid an increase in the serum sodium concentration more than 12 mEq/L (more than 12 mmol/L) in 24 hours.[1,3,30] Some recommend that the maximal rate of correction not exceed 8 mEq/L (8 mmol/L) in 24 hours.[20]

GENERAL APPROACH TO TREATMENT

The following principles serve as general guidelines for the treatment of patients with hyponatremia:[1,3,13,20,30] (1) It is important for both the short- and long-term management of the patient to treat the underlying cause of hyponatremia. (2) Appropriate treatment of patients with hypotonic hyponatremia requires balancing the risks of the hyponatremia versus the risk of osmotic demyelination syndrome. In general, patients who acutely developed moderate to severe hyponatremia and/or patients who have severe symptoms are at greatest risk and potentially benefit most from more rapid correction of their hyponatremia. (3) Active correction of hypovolemic hypotonic hyponatremia is usually best accomplished with 0.9% sodium chloride solution as these patients have both sodium and water deficits. (4) Active correction of euvolemic and hypervolemic hypotonic hyponatremia in patients who do not require rapid correction is usually best accomplished by water restriction. Demeclocycline, vasopressin V2-receptor antagonists (vaptans), or sodium chloride plus a loop diuretic, can be used if the initial response to water restriction is not adequate. In patients with severe symptoms, 3% sodium chloride solution (possibly combined with furosemide) should initially be used to more rapidly correct the hyponatremia. Furosemide can be administered concurrently to enhance the serum sodium correction by increasing the excretion of water. (5) Long-term management is required for patients in whom the underlying cause of hyponatremia cannot be corrected. This can include water restriction, increasing sodium intake, and/or the use of an AVP antagonist. Application of these principles to the treatment of patients with various forms of hypotonic hyponatremia is discussed in the following sections.

ACUTE OR SEVERELY SYMPTOMATIC HYPOTONIC HYPONATREMIA

A patient who has or is at high risk of experiencing severe symptoms caused by hyponatremia should receive either 3% or 0.9% sodium chloride solution until severe symptoms resolve.[1,3,13,20,30] Resolution of severe symptoms frequently requires only a small, 5% increase in serum sodium, although some suggest that the initial target should be to increase serum sodium to approximately 120 mEq/L (120 mmol/L).[3,31] The relative concentrations of urine sodium and potassium (osmotically effective urine cations) must be compared with those of the infusate in planning a treatment regimen for patients with hypotonic hyponatremia. For the serum sodium to increase after infusion of a solution of sodium chloride, the concentration of sodium in the infusate must exceed the sum of the sodium and potassium concentration in the urine to effect net-free water excretion.

Patients with SIADH often have urinary concentrations of osmotically effective urine cations that exceed the sodium concentration of 0.9% sodium chloride (154 mEq/L [154 mmol/L]), and thus these patients should be preferentially treated with 3% sodium chloride (513 mEq/L [513 mmol/L]). In this case use of isotonic sodium chloride carries the potential hazard of actually worsening hyponatremia.[1,31] The relatively high concentration of urinary sodium in patients with SIADH stems from the fact that the ECF is expanded, thus minimizing reabsorption of sodium along the nephron. When the urine osmolality exceeds 300 mOsm/kg (300 mmol/kg), it is generally advisable to add an intravenous loop diuretic, not only to increase the excretion of solute-free water, but also to prevent volume overload, which can result from infusion of hypertonic sodium chloride. Intravenous furosemide, initially at a dose of 40 mg every 6 hours, is generally sufficient to prevent volume overload and to decrease the concentration of osmotically active urine cations to less than 150 mEq/L (less than 150 mmol/L).

Patients with hypovolemic hypotonic hyponatremia, conversely, can be treated with 0.9% sodium chloride solution. In contrast to patients with SIADH, patients with this condition avidly reabsorb sodium throughout the nephron when the effective circulating blood volume is decreased. Thus the urine osmolality is primarily comprised of urea, and the concentration of urine sodium is often less than 20 mEq/L (less than 20 mmol/L), which is substantially less than the sodium concentration in 0.9% sodium chloride solution. Use of 3% sodium chloride solution will also effectively correct hyponatremia in these patients, but its use should be reserved for situations requiring very rapid correction.

Hypervolemic hypotonic hyponatremic patients are particularly problematic to manage acutely because the sodium and volume required to minimize the risk of cerebral edema or seizures can worsen their already compensated hepatic, cardiac, or renal function. It is generally agreed that these patients should be treated with hypertonic sodium chloride and prompt initiation of fluid restriction. Loop diuretic therapy will also likely be required to facilitate urinary excretion of free water.

DETERMINATION OF SODIUM CHLORIDE INFUSION REGIMEN

Several methods for determining the correct sodium chloride solution infusion regimen for a hyponatremic patient have been proposed.[1,3,32–36] It is important to recognize that usual approaches provide only a rough estimate of the correct infusion regimen as their use involves known but yet incorrect assumptions. More accurate equations have recently been derived, but the benefits of this more complex approach relative to the approach outlined below remain to be determined.[33,34]

One commonly used approach for estimation of the change in plasma sodium resulting from the infusion of 1 L of 3% or 0.9% sodium chloride solution is:[3,32]

Change in S_{Na} with 1 L of infusate

$$= [IV_{Na} - S^{1}_{Na}] \div (BW + IV_{vol})$$

where S^{1}_{Na} = initial patient serum sodium concentration; IV_{Na} = sodium concentration of infusate (154 mEq/L [154 mmol/L] for 0.9% sodium chloride or 513 mEq/L [513 mmol/L] for 3% sodium chloride); IV_{vol} = 1 L of infusate; and BW = total body water (in liters), which can be estimated as a fraction of body weight (kilograms) as follows[37]:

0.6 × body weight for children and men <70 years old
0.5 × body weight for men ≥70 years old and females <70 years old
0.45 × body weight for women ≥70 years old

The appropriate infusion volume for a given patient can then be estimated based on the proportion of the estimated change that would result from a 1-L infusion that is actually desired in that patient. Finally, an appropriate infusion rate can be calculated for this infusion volume to control the rate of increase in the serum sodium concentration.

For example, consider the case of a 170 centimeter (5 feet 7 inch), 60 kilogram (132 pound), 66-year-old woman who presents with nausea, vertigo, and disorientation that have developed over the past several days. She was started on carbamazepine 10 days ago for the treatment of trigeminal neuralgia. Her serum sodium is currently 108 mEq/L (108 mmol/L). Assuming this woman has carbamazepine-induced SIADH, an initial approach to treatment might include discontinuing her carbamazepine and partially correcting her hyponatremia by raising her serum sodium to approximately 120 mEq/L (120 mmol/L) over the first 24 hours of hospitalization. This should be an adequate response to alleviate her current symptoms, decrease the risk of more severe symptoms, and minimize the risk of osmotic demyelination syndrome. Assuming that use of 3% sodium chloride solution is appropriate, the infusion regimen required to increase her serum sodium to 120 mEq/L (120 mmol/L) over the next 24 hours can be calculated as follows:

Change in S^1_{Na} with 1 L of infusate =

$$(513 \text{ mEq/L} - 108 \text{ mEq/L}) \div [(0.5 \text{ L/kg} \times 60 \text{ kg}) + 1.0 \text{ L}]$$
$$= 13.1 \text{ mEq/L or } 1.31 \text{ mEq/100 mL}$$

In SI units:

$$(513 \text{ mmol/L} - 108 \text{ mmol/L}) \div [(0.5 \text{ L/kg} \times 60 \text{ kg}) + 1.0 \text{ L}]$$
$$= 13.1 \text{ mmol/L or } 1.31 \text{ mmol/100 mL}$$

Because infusion of 1 L of 3% sodium chloride solution would produce a 13.1 mEq/L (13.1 mmol/L) rise in the serum sodium, and we desire only a 12 mEq/L (12 mmol/L) increase, the appropriate infusion volume is 916 mL [(12 mEq/L ÷ 13.1 mEq/L) × 1,000 mL] or in SI units [(12 mmol/L ÷ 13.1 mmol/L) × 1,000 mL]. The approach to this calculation would be similar if 0.9% sodium chloride solution were used, except that the expected increase in serum sodium concentration would be only 1.5 mEq/L (1.5 mmol/L) per liter infused, and an infusion volume of approximately 8 L would be required to achieve the targeted serum sodium concentration.

In the presence of symptoms, the serum sodium should be increased by approximately 1.5 mEq/L (1.5 mmol/L) per hour over the first 2 to 4 hours (for a total of 3 to 6 mEq/L [3 to 6 mmol/L]) or until the symptoms have resolved. Thus, an initial infusion rate of 114 mL/h [1.5 mEq/L per hour ÷ 1.31 mEq/L per 100 mL] or [1.5 mmol/L per hour ÷ 1.31 mmol/L per 100 mL] for SI units for the first 2 to 4 hours, followed by an infusion rate of approximately 23 to 31 mL/h for the next 20 to 22 hours, respectively, would be a reasonable initial treatment plan.

CLINICAL CONTROVERSY

Clinicians often disagree whether or not to administer 3% sodium chloride to patients with symptomatic hypotonicity. Advantages of 3% sodium chloride include more rapid correction of serum sodium concentration and smaller infusion volumes. The disadvantage of 3% sodium chloride is a higher risk of exceeding maximum recommended rates of correction and causing osmotic demyelination syndrome. The clinician must carefully consider the cause of the patient's hyponatremia as well as the relative risk of slower correction of the hyponatremia versus the development of osmotic demyelination syndrome.

EVALUATION OF THERAPEUTIC OUTCOMES

Patients with severely symptomatic hypotonic hyponatremia should be admitted to the intensive care unit or to a highly monitored setting for close monitoring of neurologic and volume status. Serial physical examinations of the heart, lungs, and neurologic status should be performed several times over the initial 12 hours of hospitalization. The serum sodium concentration should be measured every 2 to 4 hours, and the urine osmolality, sodium, and potassium should be measured every 4 to 6 hours over the first day of therapy. The rate of administration of the infusate should then be adjusted to avoid exceeding a rise in the serum sodium greater than 12 mEq/L (greater than 12 mmol/L) per day.

NONEMERGENT HYPOVOLEMIC HYPOTONIC HYPONATREMIA

Most patients with hypovolemic hypotonic hyponatremia do not require rapid correction of their hyponatremia because they are either asymptomatic or have only mild-to-moderate symptoms. Many of these patients are at higher risk of developing osmotic demyelination syndrome if serum sodium correction occurs too rapidly because they have chronic hyponatremia that has been maximally compensated for by the brain's osmotic adaptation. The combination of the adaptive decrease in intracellular osmolality and rapid increase in serum osmolality results in excessive movement of water out of the brain cells, intracellular volume depletion, and thereby an increased risk of osmotic demyelination syndrome. Treatment of these patients should include correction of the underlying condition, if possible. When direct treatment of the hyponatremia is justified, a 0.9% solution of sodium chloride should be used.[1] This solution effectively replaces both the sodium and water deficits that characterize these patients and presents a lower risk of an excessive rate of correction than 3% sodium chloride solution.

A patient's ECF volume deficit (ECFVd) can be estimated based on sex, change in body weight, and age. For example, consider the case of a 56-year-old woman who was started on hydrochlorothiazide 10 days ago for the treatment of hypertension. She is 173 cm (5 ft 8 in) tall and weighed 62 kg (137 lb) at that time. Today she presents with complaints of mild nausea and "feeling dizzy" when she stands up. Her weight is now 55.5 kg (122 lb). Physical examination reveals dry mucous membranes and orthostatic hypotension. Her serum sodium is 125 mEq/L (125 mmol/L). The patient's ECFVd could be estimated as follows:[38]

$$\text{ECFVd} = \text{ECFV}_{\text{norm}} - \text{ECFV}_{\text{current}}$$
$$\text{ECFVd} = [\text{TBW}_{\text{norm}} \times 0.5 \text{ L/kg} \times 0.33] - [\text{TBW}_{\text{current}} \times 0.5 \text{ L/kg} \times 0.33]$$
$$\text{ECFVd} = [62 \text{ kg} \times 0.5 \text{ L/kg} \times 0.33] - [55.3 \text{ kg} \times 0.5 \text{ L/kg} \times 0.33]$$
$$\text{ECFVd} = 1.1 \text{ L}$$

If the patient's previous weight were not known, it could be roughly estimated based on clinical signs and symptoms. The presence of hyponatremia suggests an ECFVd of 5% or more, whereas the presence of orthostatic hypotension suggests an ECFVd of at least 10% to 15%. A 0.9% solution of sodium chloride is considered to be isotonic and thus is optimal to correct the volume deficit because it will remain in the ECF space (see Table 58–1).

The expected increase in the serum sodium concentration following infusion of 1 L of 0.9% sodium chloride (154 mEq/L [154 mmol/L]) can be estimated as:

$$\text{Change in } S_{Na} \text{ with 1 L of infusate} = [IV_{Na} - S^1_{Na}] \div (BW + IV_{vol})$$
$$= [154 \text{ mEq/L} - 125 \text{ mEq/L}] \div [(0.5 \text{ L/kg} \times 55.3 \text{ kg}) + 1.0 \text{ L}]$$
$$= 1.0 \text{ mEq/L}$$

In SI units:

$$= [154 \text{ mmol/L} - 125 \text{ mmol/L}] \div [(0.5 \text{ L/kg} \times 55.3 \text{ kg}) + 1.0 \text{ L}]$$
$$= 1.0 \text{ mmol/L}$$

The patient's sodium serum concentration can thus be predicted to be 126 mEq/L (125 mEq/L + 1.0 mEq/L) or 126 mmol/L (125 mmol/L + 1.0 mmol/L) following the infusion.

Because the overriding initial treatment goal is to restore effective circulating volume, it might be necessary to infuse 0.9% sodium chloride at 200 to 400 mL/h until symptoms of hypovolemia moderate. The infusion rate can then be decreased to 100 to 150 mL/h so that the serum sodium level increases by no more than 12 mEq/L (12 mmol/L) over the initial 24 hours. Infusion of 0.9% sodium chloride at rates greater than 250 mL/h should be used cautiously in patients with a history of left ventricular dysfunction or renal insufficiency. It is important to recognize that the rate of increase in the serum sodium concentration can substantially increase once hypovolemia has been corrected if infusion rates are not decreased.[1] Once the ECF volume is restored, AVP secretion will cease, and a rapid water diuresis can ensue, which can potentially result in an increase in the serum sodium at a rate greater than 12 mEq/L (greater than 12 mmol/L) per day. Ideally, the potential for this increase in correction rate is recognized prospectively and infusion rates are appropriately adjusted. Estimation of the patient's ECFVd at the initiation of therapy can help in this regard. If the serum sodium is observed to be increasing at a rate greater than 12 mEq/L (greater than 12 mmol/L) per day, the infusate should be changed to 0.45% sodium chloride, and the infusion rate set to one that approximates urine output (approximately 1.5–2 mL/kg per hour is a reasonable initial rate), to slow the rate of increase in the serum sodium concentration.[3]

EVALUATION OF THERAPEUTIC OUTCOMES

Patients presenting with evidence of volume depletion should be reexamined frequently during the initial few hours of therapy. The serum sodium concentration should be measured every 2 to 4 hours to allow timely adjustment of the rate and composition of intravenous fluids to avoid an increase in the serum sodium greater than 12 mEq/L (greater than 12 mmol/L) per day. Intravenous 0.9% sodium chloride should be administered judiciously in patients with a history of congestive heart failure or renal insufficiency, with frequent assessments of the cardiopulmonary examination so the infusion rate can be appropriately decreased at the earliest sign of pulmonary congestion.

NONEMERGENT EUVOLEMIC HYPOTONIC HYPONATREMIA

The fact that an individual's neurolgical performance is restored to normal with correction of their hyponatremia provides a rationale for therapeutic management of all patients to maintain their serum sodium above 135 mEq/L (135 mmol/L).[5] Long-term management is thus required for patients in whom the underlying cause of hyponatremia is not readily correctable. The treatment of SIADH always involves water restriction and correction of the underlying cause, if possible. Drugs that could be contributing should be identified and discontinued. The goal is to induce negative water balance by restricting water intake to less than 1,000 to 1,200 mL/day, such that water losses from insensible sources (skin and lung) and from obligate urine and fecal losses exceed intake. Daily insensible water losses via skin and lungs are approximately 900 mL/day, whereas approximately 200 mL and a minimum of 500 mL/day is lost in stool and in urine output, respectively. Because approximately 850 mL of water per day is ingested in food, and an additional 350 mL are generated from oxidative processes, the water intake reduction should result in a negative water balance of several hundred milliliters per day.[1] Other goals include maintenance of the serum sodium level above 125 mEq/L (125 mmol/L) to prevent symptoms of hypotonicity, and avoidance of iatrogenic hypo- or hypervolemia.

Patients with chronic SIADH who are unable to restrict water sufficiently to maintain the serum sodium greater than 120 to 125 mEq/L (greater than 120–125 mmol/L) can be treated by increasing solute intake with sodium chloride and/or loop diuretics.[3] Sodium chloride or urea tablets increase the obligatory daily solute excretion, which augments the capacity for renal water excretion. The goal is to increase the daily solute intake and excretion to approximately 900 mOsm (900 mmol) per day. Because an average diet contains approximately 600 mOsm (600 mmol), 9 grams of sodium chloride would be required to increase the osmolar excretion to 900 mOsm/day (900 mmol/day) (each 1-g sodium chloride tablet contains 17 mmol of sodium and 17 mmol of chloride). Because extracellular volume expansion is an expected adverse effect, a loop diuretic should be administered concurrently to avoid pulmonary congestion and peripheral edema. Loop diuretics also enhance water excretion by limiting the formation of the medullary concentration gradient.[39]

Demeclocycline is another treatment option for patients who are not adequately controlled by fluid restriction alone. Demeclocycline inhibits tubular AVP activity, resulting in increased water excretion.[1,40] The usual dose of demeclocycline is 300 mg 2 to 4 times daily. Because of its delayed onset of action (3–6 days), this agent has no role in the acute management of severe hyponatremia, and dosage changes should be made no more frequently than every 3 to 4 days during its use.[1,40] Demeclocycline should not be used in patients with liver disease or compromised fluid intake, who are at high risk for demeclocycline-induced renal tubular toxicity and acute renal failure, or in children because it can interfere with bone development.[1,41]

The historic therapeutic options of water restriction, diuretic therapy, and increased sodium intake have recently been augmented with the introduction of AVP antagonists or "vaptans" (Table 58–2). These agents can be used to treat SIADH, as well as other causes of euvolemic and hypervolemic hypotonic hyponatremia.[42–45]

Blockade of AVP binding can occur at one or more of its three distinct AVP receptors: V1, which are predominantly found in the liver, central nervous system, and cardiomyocytes; V2, located in the distal nephron; and V3, which are localized in the anterior pituitary and pancreas. Selective antagonism of the V2 receptor prevents aquaporin-2 water channel transport to the apical surface, thereby decreasing AVP-dependent water reabsorption in the collecting duct. This results in an increase in urine output and free-water excretion along with a decrease in urine osmolality and an increase in serum sodium. These positive outcomes are achieved without significantly increasing the excretion of electrolytes and thus these agents have been called "aquaretics."[43] Conivaptan, a mixed vasopressin V1- and V2-receptor antagonist, was approved by the FDA in 2006 for treatment of acute euvolemic hyponatremia in hospitalized patients. Because it is available only for intravenous administration and is not approved for use in patients with heart failure, its utility for the treatment of chronic hyponatremia is very limited. Several selective V2 antagonists have been investigated recently and show promise for the treatment of several chronic hyponatremic syndromes.[42–48]

Tolvaptan (Samsca; Otsuka America Pharmaceutical Company, Ltd.) is an orally active selective AVP V2-receptor blocker that received FDA marketing approval in May 2009 for the treatment of clinically significant (serum sodium <125 mEq/L [<125 mmol/L]) euvolemic or hypervolemic hyponatremia or less marked symptomatic hyponatremia that has been nonresponsive to other therapeutic interventions in patients with heart failure, cirrhosis, and SIADH.[49] It appears to be safe and effective at promoting aquaresis and raising

TABLE 58-2 Vasopressin Receptor Antagonists in Development

Drug	Company	Approval Status	Mode of Action Adminstration Route	Indication
Conivaptan (Vaprisol)	Astellas	Approved in U.S.	V1- & V2-receptor antagonist Nonselective IV limited to 4 days of use	Euvolemic hyponatremia
Tolvaptan (Samsca)	Otsuka	Approved in U.S.	V2-receptor antagonist Selective Oral	Euvolemic and hypervolemic hyponatremia
Stavaptan (SR-121463)	Sanofi-Synthelabo	Phase III	V2-receptor antagonist Selective Oral	Euvolemic and hypervolemic hyponatremia
Lixivaptan (VPA-985)	Cardiokine	Phase III	V2-receptor antagonist Selective Oral	Euvolemic and hypervolemic hyponatremia
Mozavaptan (Physuline)	Otsuka	Approved in Japan	V2-receptor antagonist Selective Oral	Euvolemic hyponatremia SIADH

serum sodium levels in both short- and intermediate-term studies (SALT-1 and SALT-2) when given alone.[48] When used alone it is superior to furosemide or fluid restriction and when given in combination synergistic effects have been noted.[50]

Tolvaptan is primarily metabolized by the CYP3A4 and less than 1% is renally eliminated unchanged; thus physicians should avoid its use in those receiving potent inhibitors of CYP3A4 such as ketaconazole, clarithromycin, itraconazole, ritonivir, etc. Concomitant therapy with P-gp inhibitors and grapefruit juice has also been noted to result in increased serum concentrations. In contrast, the optimal benefits of tolvaptan therapy may not be realized, and its dosage may need to be increased for those patients who are receiving CYP3A4 inducers such as phenytoin and St. John's Wort, etc.[49] Dose linearity has been observed within the therapeutic range and minimal accumulation, as was expected, based on its terminal half-life of 5 to 9 hours after seven plus days of therapy.[51]

Tolvaptan's recommended starting dosage is 15 mg orally once daily. If, after 24 hours, a greater increase in serum sodium concentration is needed, the dosage may be increased to 30 mg once daily and after another 24 hours, to a maximum of 60 mg once daily. Tolvaptan therapy is contraindicated in those needing rapid correction of their serum sodium concentration, those unable to sense or respond appropriately to thirst, patients with hypovolemic hyponatremia, patients taking strong CYP3A4 inhibitors, and patients who are not excreting urine.[49] Among clinical trial participants who had a serum sodium concentration of less than 125 mEq/L (less than 125 mmol/L) at the start of tolvaptan therapy, the most common adverse events were thirst, dry mouth, weakness, constipation, hyperglycemia, and urinary frequency. Although these adverse events have rarely necessitated discontinuation of therapy, FDA-approved labeling has a boxed warning stating that tolvaptan therapy should begin or resume only in a hospital where clinicians can closely monitor the patient's serum sodium concentration. The labeling also states that healthcare providers must review the product's medication guide with every patient receiving tolvaptan therapy.

The vaptans have dramatic effects on water excretion and tolvaptan represents the greatest breakthrough in the therapy of hyponatremia and disorders of fluid homeostasis since the introduction of loop diuretics. The role of vaptans in the clinical management of patients with SIADH, heart failure, and cirrhosis will likely expand as further experience is gained.

It is important to recognize that vasopressin receptor antagonists are contraindicated in hypovolemic patients as their use would worsen the hypovolemia.

EVALUATION OF THERAPEUTIC OUTCOMES

The serum sodium level should be measured every 24 to 48 hours after the water restriction is initiated until it stabilizes at a concentration of greater than 125 mEq/L (greater than 125 mmol/L). A continued decline in the serum sodium level would indicate either nonadherence to the prescribed restriction or the need for a more stringent restriction. Once the serum sodium level has stabilized above 125 mEq/L (125 mmol/L), patients should then be seen every 2 to 4 weeks to assess neurologic status and to obtain serum and urine for sodium, potassium, and osmolality. Again, attention should be given to volume status (i.e., blood pressure, mucous membranes, skin turgor, and heart and lung examination), particularly in patients who are being treated with sodium chloride tablets and loop diuretics.

NONEMERGENT HYPERVOLEMIC HYPOTONIC HYPONATREMIA

The initial treatment goals for patients with asymptomatic or minimally symptomatic hypotonic hyponatremia and an expanded ECF volume include achieving a negative water balance while minimizing rapid changes in cell volume until the serum sodium is greater than 125 mEq/L (greater than 125 mmol/L). This entails correction of the underlying cause when possible, as well as restriction of water intake to a volume less than 1,000 to 1,200 mL/day. Dietary intake of sodium should be restricted to 1,000 to 2,000 mg/day, depending on the degree of ECF volume expansion and edema.

Patients with hypervolemic hypotonic hyponatremia caused by congestive heart failure should be treated with measures that can potentially improve cardiac contractility and improve the effective circulating volume, thereby limiting the nonosmotic release of AVP. Therapeutic options include digitalis or afterload reduction with angiotensin-converting enzyme inhibitors (ACEIs) or angiotensin II receptor blockers (ARBs). Of these, only ACEIs have been shown in clinical trials to be of benefit in partially correcting hyponatremia in patients with congestive heart failure.[52] No specific ACE inhibitor offers any particular advantage for this indication, and the dose should be titrated to keep the systolic blood pressure in the 110 to 130 mm Hg range. Dose-limiting adverse effects include hyperkalemia (serum potassium >5.5 mEq/L [>5.5 mmol/L]), as well as a decline in renal function. The benefits and risks of continuing ACE inhibition must be weighed carefully in each case, but a decrease

in glomerular filtration rate (GFR) of less than 30% that stabilizes within 2 months of therapy initiation generally does not require dosage reduction or discontinuation of the ACE inhibitor.[53]

CLINICAL CONTROVERSY

Some clinicians regard any increase in serum creatinine in patients on ACEIs as a reason to decrease dosage or discontinue the medication. ACEIs selectively dilate the afferent arteriole, causing a decrease in intraglomerular pressure and reduced GFR. Although this might be viewed negatively, many experts suggest that the decrease in pressure is likely renoprotective, and that one does not need to reduce the dosage or discontinue therapy unless the resulting decrease in GFR is greater than 30% and does not stabilize within 2 months.

Other potentially treatable causes of asymptomatic hyponatremia associated with an expanded ECF volume include nephrotic syndrome and cirrhosis. ACEIs can be used to decrease proteinuria in patients with nephrotic syndrome, leading to partial correction of hypoalbuminemia and to a decrease in nonosmotic AVP release. Patients with advanced cirrhosis can benefit from placement of a transjugular intrahepatic portosystemic shunt, which can increase the effective circulating volume and thus reduce the nonosmotic release of AVP. This procedure can potentially exacerbate or precipitate hepatic encephalopathy, and should be avoided in patients with a history of encephalopathy.

Vasopressin receptor antagonists have also been proposed for the treatment of hypervolemic hypotonic hyponatremia in patients with congestive heart failure and cirrhosis.[42–45,54,55] The effectiveness of tolvaptan in the short-term management of heart failure patients with hypervolemic hyponatremia has been evidenced by decreased body weight, increased urine output, decreased pulmonary capillary wedge pressure, and decreases in urine osmolality.[56–61] Long-standing beneficial effects, reduction in hospitalization or death, or progression of heart failure have not been observed in several pivotal trials.[58,60,62] Prolonged use of tolvaptan leads to increased endogenous levels of AVP and some have theorized that this overstimulation of V(1A)-receptors could lead to increased afterload and progression of HF.[63] However, after 52 weeks of tolvaptan therapy (30 mg daily) no worsening of left ventricular dilatation was observed by Udelson and colleagues.[62]

EVALUATION OF THERAPEUTIC OUTCOMES

Patients should initially be evaluated on a daily basis for lung congestion, ascites, peripheral edema, and signs or symptoms of hyponatremia. The serum sodium concentration should be measured daily until it stabilizes above 125 mEq/L (125 mmol/L) following initiation of water restriction. Patients should then be assessed 1 week following discharge, and then every 2 to 4 weeks to assess compliance with the water restriction and other treatment measures, volume status, and hyponatremia-related symptoms.

HYPERNATREMIA

EPIDEMIOLOGY AND ETIOLOGY

5 Hypernatremia (serum sodium >145 mEq/L [>145 mmol/L]) is always associated with hypertonicity and results from a deficit of water relative to ECF sodium content.[1] Hyperosmolar states are a potent stimulus for thirst, and therefore hypernatremia is most commonly observed in patients with an impaired thirst response or in those without access to water. Infants and comatose patients, as well as elderly or disabled patients with an impaired sensorium or functional status are therefore at highest risk for this disorder.[64] The incidence of hypernatremia in general medical-surgical hospital patients and intensive care unit patients has been estimated to be at least 1% and 7.9%, respectively.[65,66] Outcome generally depends on the rapidity with which the hypernatremia developed. Mortality from acute hypernatremia in children, which develops in less than 72 hours, ranges from 10% to 70%. In contrast, chronic hypernatremia in children, defined as that which develops over 3 or more days, has a mortality rate of 10%.[67] An acute increase in serum sodium in adults to greater than 160 mEq/L (greater than 160 mmol/L) is associated with a 75% mortality rate.[35] Adults in whom the hypernatremia developed at a slower rate have a lower but still high mortality rate of approximately 60%. Hypernatremia in adults is often associated with a serious underlying illness, which likely contributes to the high mortality rate.

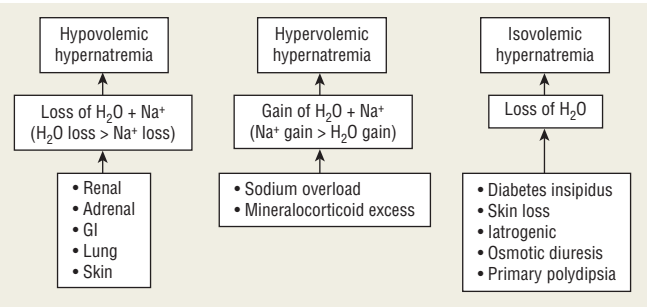

FIGURE 58-3. Common etiologies of hypernatremia. (H_2O, water; Na^+, sodium.)

PATHOPHYSIOLOGY

Hypernatremia can result from either loss of water or hypotonic fluids, or less commonly from administration of hypertonic fluids or ingestion of sodium. Patients develop hypovolemic, hypervolemic, or isovolemic hypernatremia depending on the relative magnitude of sodium and water loss or gain caused by the underlying condition (Fig. 58–3).

Water loss commonly occurs as a result of insensible losses (evaporative losses of water through the skin and lungs) in patients deprived of water. Hospitalized patients who are febrile or receiving mechanical ventilation are often treated with intravenous fluids containing insufficient free water to replace insensible losses. Hypernatremia can be observed in patients with hypotonic gastrointestinal losses (diarrhea or vomiting) or in patients who have been exposed to high temperatures who suffer large water losses from both sweat and insensible losses.

Diabetes insipidus (DI) is a condition characterized by decreased AVP secretion or decreased renal response to AVP.[1,68,69] Patients excrete large volumes (3 to 20 L/day) of dilute urine, resulting in large urinary losses of water. DI is classified as either central (decreased AVP secretion) or nephrogenic (decreased renal response to AVP). Table 58–3 summarizes the causes of DI. Patients with central DI often present with sudden onset of polyuria, whereas patients with nephrogenic DI develop polyuria more gradually.

Administration of hypertonic sodium chloride can result in hypernatremia and an expanded ECF volume. This is typically iatrogenic, and can follow administration of sodium bicarbonate, use of hypertonic sodium chloride enemas, or intrauterine injection of hypertonic sodium chloride. Rarely, patients with hyperaldosteronism spontaneously present with an expanded ECF and mild hypernatremia.[64]

TABLE 58-3 Causes of Diabetes Insipidus

Central DI	Nephrogenic DI
Idiopathic	Lithium toxicity
Familial	Hypercalcemia
Neurosurgery	Hypokalemia

CLINICAL PRESENTATION

6 The symptoms of hypernatremia are primarily caused by a decrease in neuronal cell volume and can include weakness, lethargy, restlessness, irritability, and confusion.[1,64] Symptoms of more severe or rapidly developing hypernatremia include twitching, seizures, coma, and death. Hypernatremia results in movement of water from the intracellular space to the extracellular fluid. As discussed above, neurons can adapt to ECF tonicity changes by adjusting intracellular osmolality, including decreasing or increasing the concentration of organic osmolytes. In the case of hypernatremia, ECF hypertonicity results in generation of intracellular organic osmolytes within 24 hours of onset. This increase in intracellular fluid tonicity then draws water into the neurons, thus limiting the decrease in cell volume. Patients with chronic hypernatremia are therefore less likely to present with symptoms caused by this cerebral adaptation than patients with acute hypernatremia.

CLINICAL PRESENTATION OF HYPERNATREMIA

General

- The rise in the plasma sodium concentration and osmolality causes acute water movement from the intracellular to the extracellular fluid. In the brain this decrease in volume can cause rupture of the cerebral veins, leading to focal intracerebral and subarachnoid hemorrhages and possible irreversible neurologic damage.

Symptoms

- The clinical manifestations of this disorder begin with lethargy, weakness, confusion, restlessness, and irritability, and can progress to twitching, seizures, coma, and death. Severe symptoms usually require an acute elevation in the plasma sodium concentration to above 160 mEq/L (160 mmol/L). Values >180 mEq/L (>180 mmol/L) are associated with a high mortality rate.

Signs

- Signs of hypernatremia can include postural hypotension, tachycardia, dry oral mucosa, diminished skin turgor, and reduced or increased output of dilute or concentrated urine, depending on cause.
- Signs associated with chronic hypernatremia are often difficult to detect because most affected adults have underlying neurologic disease.

Laboratory Tests

- Serum sodium levels are generally >145 mEq/L (>145 mmol/L). Measurement of urine volume and osmolality may be helpful in diagnosing the cause.

Hypernatremia is often associated with serious underlying illness, and signs and symptoms related to that illness can also be present. Patients with a history of severe diarrhea or vomiting can present with ECF volume depletion. Elderly patients deprived of water after sustaining a stroke or hip fracture often present with mental status changes and signs of ECF volume depletion. Clinically detectable extracellular fluid volume depletion, however, might not be evident until the serum sodium concentration exceeds 160 mEq/L (160 mmol/L), because these patients primarily have water loss, two thirds of which is derived from the intracellular space. The urine is concentrated, osmolality often exceeds 450 mOsm/kg (450 mmol/kg), as a result of both osmotic and nonosmotic release of AVP. The first step in evaluating patients with hypernatremia is the clinical assessment of the ECF volume, urine volume, and urine osmolality (Fig. 58–4).

Patients with a contracted ECF volume and a low urine output include those who have sustained insensible water losses that exceed intake, as well as those with extrarenal losses of hypotonic fluids. On physical examination, one should search for postural hypotension, diminished skin turgor, and delayed capillary refill. The daily urine output is typically less than 1 L.

A recent multicenter, case-control study examined the clinical presentation of hypernatremia in 150 elderly patients in geriatric care facilities.[70] Low blood pressure, tachycardia, dry oral mucosa, decreased skin turgor, and recent changes in consciousness were all more common in hypernatremic patients than in controls. Perhaps not surprisingly in this mixed patient population, the presence of signs of dehydration was variable, with orthostatic hypotension and decreased subclavicular and forearm skin turgor present in at least 60% of patients. Abnormal subclavicular and thigh skin turgor, dry oral mucosa, and recent change in consciousness were significantly and independently associated with hypernatremia.

Osmotic Diuresis

Patients undergoing an osmotic diuresis generally have urine volumes greater than 3 L/day. Excessive urinary excretion of glucose, sodium, urea, or an exogenously administered solute such as mannitol are identified either by history or by direct measurement of serum and urinary concentrations of the suspected solute. Patients with postobstructive diuresis, such as those with bladder outlet obstruction caused by prostatic hypertrophy, are usually volume expanded as a result of retained excess solute because of a decline in the GFR.[1] The osmotic diuresis that follows alleviation of the obstruction is appropriate in that it promotes excretion of the excess retained solute. Patients with severe hyperglycemia, conversely, present with signs of volume depletion, and the diuresis is therefore inappropriate, further exacerbating the degree of ECF volume contraction.

Diabetes Insipidus

Patients with DI tend to maintain a normal ECF volume as long as they are conscious and have free access to water. Patients typically have only a slight elevation in the serum sodium concentration (usually in the 141–145 mEq/L [141–145 mmol/L] range), and a daily urine volume greater than 3 L.[71] A water deprivation test is sometimes recommended to aid in the differential diagnosis between central and nephrogenic DI.[30] This consists of depriving patients of water for 8 to 12 hours. Urine osmolality, urine volume, and body weight are then measured before and after subcutaneous administration of 5 mcg of desmopressin acetate. Patients with central DI will show a prompt increase in urine osmolality to approximately 600 mOsm/kg (600 mmol/kg) and a decrease in urine volume after desmopressin administration. Those with nephrogenic DI will be unable to increase the urine osmolality above 300 mOsm/kg (300 mmol/kg).[1] The direct measurement of

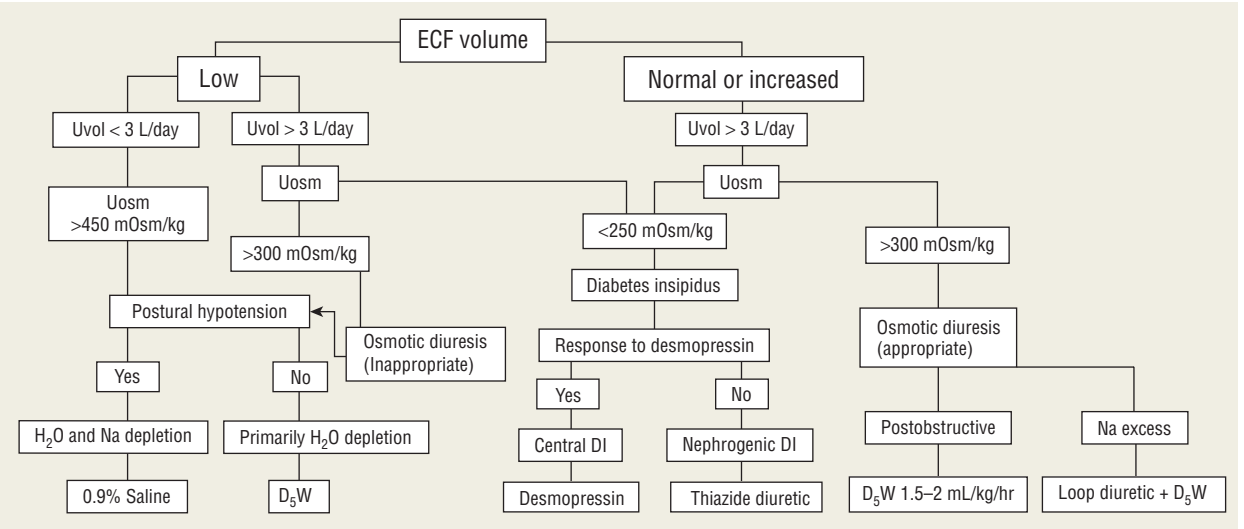

FIGURE 58-4. Diagnostic and treatment algorithm for hypernatremia. (D_5W, 5% dextrose in water; ECF, extracellular fluid; H_2O, water; Na, sodium; Uosm, urine osmolality [values in mOsm/kg are numerically equivalent to mmol/kg]; Uvol, daily urine volume.) See text for guidelines regarding calculations of infusion rates for intravenous solutions.

vasopressin levels after infusion of 5% sodium chloride at a rate of 0.05 mL/kg/min for no more than 2 hours improves the accuracy of diagnosis, but carries a high risk of ECF volume overload.[72]

The value of performing a water deprivation test in patients with polyuria and hypernatremia, such as patients with DI, has recently been questioned.[73] Because hypernatremia provides a maximal stimulus for AVP secretion, discriminating between nephrogenic and central DI can be based on plasma vasopressin concentration and urinary response to desmopressin without the need for water deprivation. The water deprivation test is thus likely to only be of diagnostic value in patients with polyuria and a normal serum sodium concentration.

Sodium Overload

Patients who have ingested large amounts of sodium (>4 tablespoons [1,400 mEq or 1,400 mmol Na^+] of sodium chloride) or who have received greater than 5 L of hypertonic fluids are volume expanded, although this may not always be clinically evident as edema. This results in an osmotic diuresis, polyuria, and a urine osmolality greater than 300 mOsm/kg (greater than 300 mmol/kg). The excess sodium will be excreted in the urine in patients with normal renal function.

TREATMENT

Hypernatremia

DESIRED OUTCOME

7 The desired goals for patients with hypernatremia include correction of the serum sodium concentration at a rate that restores and maintains cell volume as close to normal as possible, as well as normalizing the ECF volume in states of ECF volume depletion or expansion. Adequate treatment should result in the resolution of symptoms associated with hypovolemia. Careful titration of fluids and medications should minimize the adverse effects from too rapid correction. Rapid correction can result in movement of excessive water into the brain cells, resulting in cerebral edema, seizures, neurologic damage, and potentially death.[1] Modulation of dietary sodium intake and sodium replacement can be necessary to prevent recurrence of hypernatremia.

PHARMACOLOGIC THERAPY

Hypovolemic Hypernatremia

Hypovolemic hypernatremia should initially be treated with 0.9% sodium chloride until hemodynamic stability is restored. An initial infusion rate of 200 to 300 mL/h will likely be appropriate for many patients. Once intravascular volume is restored, 0.45% sodium chloride or 5% dextrose in water can then be infused to correct the water deficit,[38] the volume of which can be estimated as:

$$\text{Water deficit} = \text{Present TBW} \times [(S^1_{Na}/140) - 1]$$

where TBW = total body water; S^1_{Na} = initial patient serum sodium concentration (in mEq/L [or mmol/L]); and 140 = normal or goal S_{Na} (in mEq/L [or mmol/L]).

The rate of correction depends on the rapidity with which the hypernatremia developed. Hypernatremia that has developed over a few hours can be initially corrected at a rate of approximately 1 mEq/L (1 mmol/L) per hour, whereas a rate of 0.5 mEq/L (0.5 mmol/L) per hour should be used when it has developed more slowly.[20,64] The rate of correction should generally be limited to no more than 10 mEq/L (10 mmol/L) per day.[30,64]

Treatment of hyperglycemia-induced osmotic diuresis consists of correcting the hyperglycemia with insulin, as well as administering 0.9% sodium chloride until signs of ECF volume depletion resolve. Once hemodynamic stability is restored, the water deficit should be corrected in a manner analogous to that described for patients with hypovolemic hypernatremia above. The corrected serum sodium level should be calculated by adding 1.7 mEq/L (1.7 mmol/L) for every 100 mg/dL (5.6 mmol/L) increase in the serum glucose concentration before estimating the water deficit.[3]

Hypernatremia in patients undergoing a postobstructive diuresis should be treated with infusion of hypotonic fluids such as 0.45% sodium chloride at maintenance rates of approximately 1.5 mL/kg per hour. It is important to avoid the temptation to administer fluids to replace urine output on a 1:1 volume basis, because this tends to perpetuate the diuresis.

The serum sodium concentration and fluid status should be monitored every 2 to 3 hours over the first 24 hours of admission in patients with symptomatic hypernatremia to permit appropriate adjustment in the rate of infusion of hypotonic fluids. After

TABLE 58-4 Drugs Used to Manage Central and Nephrogenic Diabetes Insipidus

Drug	Indication	Dose
Desmopressin acetate	Central and nephrogenic	5–20 mcg intranasally every 12–24 h
Chlorpropamide	Central	125–250 mg orally daily
Carbamazepine	Central	100–300 mg orally bid
Clofibrate	Central	500 mg orally qid
Hydrochlorothiazide	Central and nephrogenic	25 mg orally q 12–24 h
Amiloride	Lithium-related nephrogenic	5–10 mg orally daily
Indomethacin	Central and nephrogenic	50 mg orally q 8–12 h

symptoms resolve and the serum sodium is less than 148 mEq/L (less than 148 mmol/L), serum sodium determinations every 6 to 12 hours and fluid status assessment every 8 to 24 hours are generally sufficient to follow the course of therapy.

Central Diabetes Insipidus

8 Patients with central DI should generally receive AVP replacement therapy with desmopressin, an AVP analog.[1,20] Because of variable absorption of oral desmopressin, DI is best treated with the intranasal formulation 1-desamino-8-D-arginine vasopressin (DDAVP); however, oral tablets are available and can be useful in some patients. The beginning intranasal dose should be 10 mcg once daily. Ultimately, the dose may need to be titrated up to 10 mcg twice daily for most adults. Each insufflation of intranasal DDAVP delivers 10 mcg of desmopressin acetate at a concentration of 100 mcg/mL. Several medications with antidiuretic properties have been used successfully in the management of central and nephrogenic DI (Table 58–4). They can be used as an alternative to DDAVP or adjunctively.

The desmopressin dose should be adjusted to achieve adequate urinary concentration during sleep to prevent nocturia, to result in a daily urine volume of approximately 1.5 to 2 L, and to maintain the serum sodium concentration in the 137 to 142 mEq/L (137–142 mmol/L) range. The serum sodium concentration should be measured every 3 to 4 days during the initial dose titration period, and then every 2 to 4 months. Administration of desmopressin results in nonsuppressible AVP activity and presents a risk of water intoxication caused by excess water retention.[1] Patients using desmopressin should therefore be monitored for signs and symptoms of hyponatremia and hypervolemia. It has been suggested that patients using desmopressin who experience water intoxication can minimize the risk of a second episode by delaying a dose of desmopressin each week until polyuria and thirst develop, thus demonstrating the need for additional desmopressin doses.[20]

Nephrogenic Diabetes Insipidus

Hypercalcemia and hypokalemia should be corrected, and medications that contribute to the pathogenesis should be discontinued. One key goal in treating nephrogenic DI is to induce a mild ECFVd (1–1.5 L) with a thiazide diuretic and dietary sodium restriction (85 mEq [85 mmol] Na^+ or 2,000 mg sodium chloride per day), which often can decrease urine volume by as much as 50% (see Table 58–4). This will increase proximal water reabsorption, decrease the volume of filtrate delivered to the distal nephron, and decrease urine volume. NSAIDs such as indomethacin at a dose of 50 mg 3 times a day can potentiate the activity of AVP and can be used as adjunctive therapy.[1,74] Patients with lithium-induced nephrogenic DI can derive particular benefit from amiloride at a dose of 5 to 10 mg daily; amiloride directly inhibits uptake of lithium from the tubular lumen into principal cells in the cortical collecting duct.[1,75]

CLINICAL CONTROVERSY

The relative merits of the various drug treatment options, including NSAIDs and amiloride, for nephrogenic DI have not been well studied. Choice of agents is therefore subject to clinician variability. It is unclear if there is a significant difference among these agents in the risk of clinically important decreases in GFR when they are used to produce mild ECF volume decreases.

EVALUATION OF TREATMENT OUTCOMES

Physical examination with attention to volume status and measurement of serum and urine sodium concentration and osmolality should be assessed every 2 to 3 months during chronic therapy. A 24-hour urine collection to measure urine volume and sodium excretion will help guide therapy with diuretics and determine adherence to sodium restriction.

Sodium Overload

Treatment of sodium overload consists of administration of loop diuretics to facilitate excretion of the excess sodium, as well as intravenous D_5W. The latter should be infused at a rate that will decrease the serum sodium at approximately 0.5 mEq/L (0.5 mmol/L) per hour, or 1 mEq/L (1 mmol/L) per hour in cases in which the hypernatremia developed rapidly over several hours.[64] The volume of infusate may be estimated as described previously. Furosemide should be administered at a dose of 20 to 40 mg intravenously every 6 hours.

The serum sodium should initially be measured every 2 to 4 hours, and the diuretic continued until signs of ECF volume overload (pulmonary congestion and edema) resolve. The serum sodium concentration can be determined every 6 to 12 hours once the serum sodium level is less than 148 mEq/L (less than 148 mmol/L) and symptoms of hypertonicity resolve.

EDEMA

The body closely monitors blood volume to help ensure adequate tissue perfusion. A decline in the effective circulating volume (actually the blood pressure resulting from that volume) results in decreased sodium and water excretion by the kidney.[1] Under these conditions, the kidneys retain all the water and sodium ingested until the effective circulating volume is restored to normal. An increase in dietary sodium is accompanied by an increase in water intake caused by the initial increase in serum osmolality and stimulation of thirst. The resultant increase in ECF volume augments renal perfusion, effecting a transient increase in GFR which leads to enhanced sodium filtration and excretion.[76] These homeostatic mechanisms are crucial in maintaining sodium balance, as retention of just a few milliequivalents (mmoles) of sodium per day can eventually lead to an expanded ECF volume and edema formation.

PATHOPHYSIOLOGY

9 Edema may be defined as a clinically detectable increase in interstitial fluid volume. Clinical detectability in adults generally requires an interstitial volume increase of at least 2.5 to 3 L.[1] Edema develops when excess sodium is retained either as a primary defect in renal sodium excretion, or as a response to a decrease in the effective circulating volume despite a normal or expanded ECF volume. An increase in the capillary hydrostatic pressure because of

an expansion of the ECF volume, or an increase in central venous pressure may lead to edema formation. Edema may also occur when there is an alteration in Starling forces within the capillary.[77] The Starling equation denotes the relationship between factors affecting the movement of fluid between the capillary and interstitium and is discussed in detail in Chapter 30.

Edema may develop rapidly in those with an acute decompensation in myocardial contractility which leads to an elevation in pulmonary venous pressure that is transmitted back to the pulmonary capillaries and ultimatley results in acute pulmonary edema. Edema may also develop insidiously as in the case of renal sodium and water retention due to diminished effective circulating volume which leads to a rise in the ECF volume and edema formation in both peripheral and pulmonary interstitial tissues.

Edema formation in patients with nephrotic syndrome is primarily related to renal sodium and water retention. A decrease in capillary oncotic pressure does not appear to play a major role until the serum albumin concentration less than 2 g/dL (less than 20 g/L). This is explained by the fact that both capillary and interstitial oncotic pressure decrease proportionately above a serum albumin concentration of 2 g/dL (20 g/L), and thus the transcapillary oncotic gradient is not significantly altered.[78]

Patients with cirrhosis initially develop ascites as a result of an increase in the pressure in the portal circulation proximal to the diseased liver. Sequestration of fluid in the abdominal cavity (ascites) and peripheral vasodilation as a consequence of increased levels of circulating cytokines, result in a decrease in the effective circulating volume, activation of the sympathetic nervous system, and secondary hyperaldosteronism. Therefore, renal sodium retention leads to worsened ascites and edema.

CLINICAL PRESENTATION

Edema is usually first detected in the feet or pretibial area of ambulatory patients and in the presacral area of bed-bound individuals. Edema is described as "pitting" when a depression created by exerting pressure for several seconds over a bony prominence such as the tibia does not rapidly refill. The severity of the edema should be rated on a semi-quantitative scale of 1+ to 4+ depending on the depth of the pit (1+ = 2 mm, 2+ = 4 mm, 3+ = 6 mm, and 4+ = 8 mm).

The extent of the edema should also be quantified according to the area of involvement. Pretibial edema, for example, should be quantified according to how far it extends up the lower leg (e.g., one-third up the lower leg). Pulmonary edema, an increase in lung interstitial and alveolar water, is often evidenced by crackles (also called rales) upon auscultation. It should be quantified according to how far the crackles extend from the dependent portion of the lung(s). So, for example, edema limited to the ankles and feet would indicate less severe edema than edema that extends halfway up the lower legs, and crackles limited to the base of both lungs in an upright person would indicate less severe pulmonary edema than crackles throughout both lung fields.

TREATMENT

Edema

GENERAL APPROACH TO TREATMENT

⑩ The goals of therapy are to minimize tissue edema and thus improve organ function, as well as to relieve symptoms of edema such as dyspnea in patients with CHF or abdominal distention in patients with ascites. It is important to emphasize that the presence of edema does not always dictate the need for instituting pharmacologic (diuretic) therapy. Only pulmonary edema requires immediate pharmacologic treatment because it is life-threatening. Other forms of edema may be treated gradually, with a comprehensive approach that includes not only diuretics, but also sodium restriction and treatment of the underlying disease state. Sodium intake should generally be restricted to 1,000 to 2,000 mg/day. A slow, more judicious approach in non-life-threatening situations will help to minimize complications of diuretic therapy and excessive fluid removal. These may include impaired vital organ perfusion, azotemia, and impaired cardiac output due to a fall in the left ventricular end-diastolic filling pressure.

PHARMACOLOGIC THERAPY

Diuretics are the primary pharmacologic therapy for the management of edema. Patients with expanded ECF volume and edema often require therapy with diuretics when treatment of the underlying disease and daily sodium restriction are insufficient to relieve the edema. Diuretics can be categorized according to the site in the nephron where sodium reabsorption is inhibited. Loop diuretics inhibit the sodium-potassium-chloride (Na^+-K^+-$2Cl^-$) carrier in the loop of Henle. Thiazide diuretics inhibit the Na^+-Cl^- carrier in the distal tubule. Finally, potassium-sparing diuretics inhibit the sodium channel in the cortical collecting duct either directly (triamterene and amiloride), or by interfering with aldosterone activity (spironolactone and eplerenone). The efficacy of a diuretic depends on the presence of several factors, including the amount of filtered solute normally reabsorbed at the site of action, the amount of solute reabsorbed distal to the site of action, and adequate delivery of drug to the site of action in the nephron.

Loop diuretics are the most potent diuretics, as evidenced by the fact that they increase peak fractional excretion of sodium (FeNa) to 20% to 25% (0.20–0.25). Thiazide- and potassium-sparing diuretics are less potent and increase peak FeNa to 3% to 5% (0.03–0.05) and 1% to 2% (0.01–0.02), respectively.[1] Although

TABLE 58-5 Maximal Effective Dose and Dosing Interval for Edema Management with Loop Diuretics

Diuretic	Dosing Interval	Normal	Cirrhosis	CHF	Nephrotic Syndrome	GFR (10–50 mL/min)	GFR (<10 mL/min)
Furosemide							
IV	6–8 h	10–40 mg	40 mg	40–80 mg	120 mg	80 mg	200 mg
Oral	6–8 h	20–80 mg	80 mg	80–160 mg	240 mg	160 mg	320–400 mg
Bumetanide							
IV/Oral	6–8 h	1 mg	1 mg	2–3 mg	3 mg	2–3 mg	8–10 mg

CHF, congestive heart failure; GFR, glomerular filtration rate.

a large portion of the filtered sodium is reabsorbed in the proximal nephron, the efficacy of proximal-acting diuretics such as acetazolamide is limited by reabsorption of the excess fluid and sodium in the loop of Henle.

The effectiveness of thiazide and loop diuretics is dependent on the concentration of the drug in the tubular lumen. These diuretics are delivered to the tubular lumen of the kidney by active transport by the proximal tubular cells. Osmotic diuretics, conversely, are freely filtered into the tubular lumen in the proximal tubule, whereas spironolactone gains access to mineralocorticoid receptors in the cortical collecting duct through diffusion from the systemic circulation.

A threshold concentration of loop or thiazide diuretic must be delivered to the active site (e.g., loop of Henle or distal tubule) to achieve a natriuresis.[1,79] Once this concentration is achieved, further increases in diuretic dose will not elicit an increase in diuretic response. Thus a ceiling dose of these diuretics is recognized. Administration of 40 mg of intravenous furosemide to a normal subject will result in excretion of 200 to 250 mEq (200–250 mmol) of sodium in 3 to 4 L of urine over a 3- to 4-hour period.[79] Table 58–5 summarizes the maximal effective doses and dosing intervals for loop diuretics in patients with cirrhosis, CHF, nephrotic syndrome, as well as those with reduced renal function.

Patients with renal insufficiency often require larger doses of diuretics to achieve adequate concentrations of the drug at the active site. The natriuretic response is decreased in patients with renal insufficiency because the filtered load of sodium falls proportionately as GFR declines. This can be partially overcome by dosing diuretics more frequently, as well as by using continuous infusions in critically ill hospitalized patients.[1,80,81] The latter will maintain more consistent levels of the diuretic above the threshold concentration. Patients who are diuretic resistant should be treated with both a loop and a thiazide-type diuretic. Patients with CHF and a normal GFR may have impaired oral absorption of furosemide. An adequate diuresis is most readily sustained by increasing the frequency of diuretic administration (Fig. 58–5).

Diuretic resistance can be caused by increased uptake of sodium in the distal tubule, impaired delivery of diuretics to the site of action, or decreased intrinsic diuretic activity. Animal studies have demonstrated binding of furosemide to albumin in the tubular lumen, which decreases the availability of the drug to the active site.[82] Human studies, however, have demonstrated that when albumin binding is inhibited by concurrent administration of sulfasoxazole, diuretic resistance persists, suggesting a decrease in intrinsic tubular sensitivity to loop diuretics.[83] This impaired natriuretic response can be overcome by using higher diuretic doses to increase the delivery of free drug to the secretory site in the nephron.[80,81] Combinations of loop diuretics with distally acting diuretics are generally necessary to promote a natriuresis that exceeds tubular sodium reabsorption for those with nephrotic syndrome (Fig. 58–6).

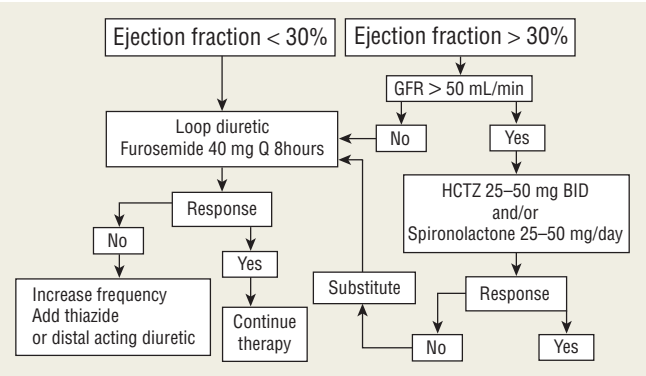

FIGURE 58-5. Therapeutic algorithm for diuretic use in patients with congestive heart failure. (GFR, glomerular filtration rate [50 mL/min is equivalent to 0.84 mL/s]; HCTZ, hydrochlorothiazide.)

CLINICAL CONTROVERSY

Some clinicians advocate using combinations of diuretics in cases of diuretic resistance associated with nephrotic syndrome, while others prefer to use larger-than-average doses of single agents to overcome enhanced protein binding in the tubular lumen associated with proteinuria.

Secondary hyperaldosteronism plays a major role in the pathogenesis of edema in patients with cirrhosis. Therefore, these patients should initially be treated with spironolactone in the absence of impaired GFR and hyperkalemia. Thiazides can then be added for patients with a creatinine clearance >50 mL/min (>0.84 mL/s). For those patients who remain diuretic resistant, a loop diuretic can replace the thiazide. Patients with impaired GFR (creatinine clearance of <40 mL/min [<0.67 mL/s]) can require a loop diuretic, with addition of a thiazide in those who do not achieve adequate diuresis.[81] Care should be taken to avoid hypokalemia, which can precipitate hepatic encephalopathy by increasing ammoniagenesis (Fig. 58–7).[84]

Complications of loop and thiazide diuretic therapy include hypokalemia, excess depletion of ECF volume, hyponatremia, hypomagnesemia, metabolic alkalosis, and hyperuricemia. Thiazides can also cause hypercalcemia, particularly in patients with mild subclinical hyperparathyroidism. Chronic therapy with potassium-sparing diuretics, including triamterene, amiloride, and spironolactone, can cause a mild metabolic acidosis and can precipitate hyperkalemia. Patients with moderate to severe kidney dysfunction or those receiving NSAIDs, ACEIs, or ARBs are

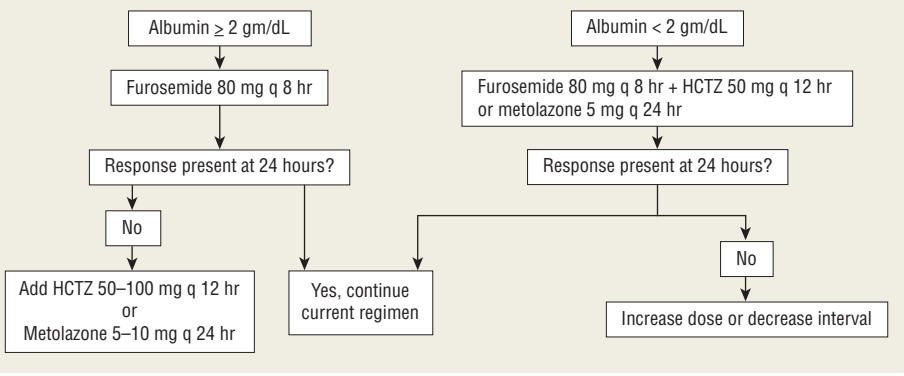

FIGURE 58-6. Therapeutic algorithm for diuretic therapy in patients with nephrotic syndrome. Albumin concentration of 2 gm/dL is equivalent to 20 g/L. (HCTZ, hydrochlorothiazide.)

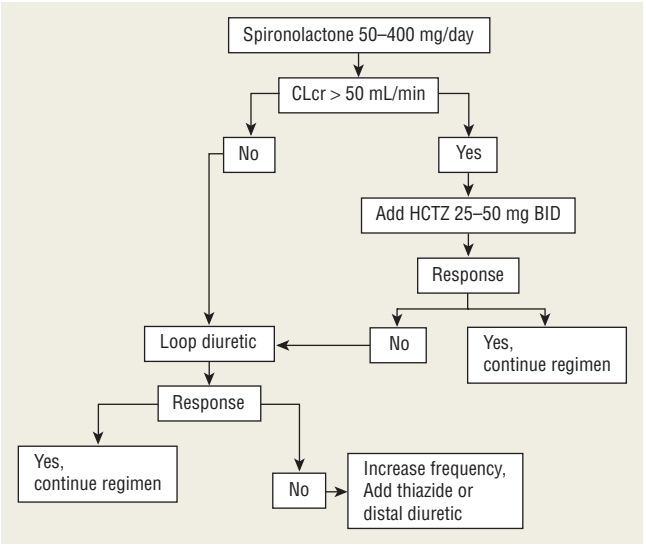

FIGURE 58-7. Therapeutic algorithm for diuretic use in patients with cirrhosis. (CL_{cr}, creatinine clearance [50 mL/min is equivalent to 0.84 mL/s]; HCTZ, hydrochlorothiazide.)

at highest risk for this complication. In addition, spironolactone can cause reversible gynecomastia in patients receiving therapy for more than several weeks. This side effect, however, has not been associated with eplerenone, a newly available aldosterone antagonist.[85]

EVALUATION OF THERAPEUTIC OUTCOMES

Patients should be monitored by careful history and intermittent physical examinations to detect signs and symptoms of edema as well as adverse effects of treatment. Physical examination should include measurement of blood pressure and pulse in either supine or seated positions and after standing for 2 to 3 minutes. ECF volume can be estimated based on the height of the jugular venous pressure, extent of edema, auscultation of the heart and lungs, and skin mobility. Followup monitoring (10–14 days after initiation of therapy) should include determinations of serum sodium, potassium, chloride, bicarbonate, magnesium, calcium, BUN, serum creatinine, and uric acid. A new steady state will have developed over that time period and further fluctuations in ECF volume and electrolyte balance should not occur in the absence of a change in clinical status, diuretic dose, or dietary intake. Repeated blood tests are not necessary at every visit unless there is a change in the patient's clinical status.

ABBREVIATIONS

ACEI: angiotensin-converting enzyme inhibitor

AVP: arginine vasopressin, also known as antidiuretic hormone or ADH

ATPase: adenosine triphosphatase

BUN: blood urea nitrogen

CHF: congestive heart failure

CNS: central nervous system

DDAVP: 1-desamino-8-D-arginine vasopressin

D_5W: 5% dextrose in water

DI: diabetes insipidus

ECF: extracellular fluid

ECFVd: extracellular fluid volume deficit

$ECFV_{current}$: current extracellular fluid volume

$ECFV_{norm}$: normal extracellular fluid volume

FeNa: fractional excretion of sodium

GFR: glomerular filtration rate

IV_{Na}: sodium concentration of infusate

IV_{vol}: volume of infusate

NSAID: nonsteroidal antiinflammatory drug

S^1_{Na}: initial patient serum sodium concentration

SIADH: syndrome of inappropriate secretion of antidiuretic hormone

TBW: total-body water

$TBW_{current}$: current total-body water

TBW_{norm}: normal total-body water

CHAPTER 59

Disorders of Calcium and Phosphorus Homeostasis

AMY BARTON PAI

KEY CONCEPTS

1. Severe acute hypercalcemia can result in cardiac arrhythmias, whereas chronic hypercalcemia can lead to calcium deposition in soft tissues including blood vessels and the kidney.
2. The correction of hypercalcemia can include multiple pharmacotherapeutic modalities such as hydration, diuretics, bisphosphonates, and steroids, depending on the etiology and acuity of the hypercalcemia.
3. Hypocalcemia is typically associated with an insidious onset; however, some drugs such as cinacalcet are associated with rapid decreases in serum calcium.
4. Acute treatment of hypocalcemia requires calcium supplementation whereas chronic management may require other therapies such as vitamin D to maintain serum calcium values.
5. Hyperphosphatemia occurs most frequently in patients with chronic kidney disease.
6. Treatment of nonemergent hyperphosphatemia includes the use of phosphate binders to decrease absorption of phosphorus from the gastrointestinal tract.
7. Hypophosphatemia is a relatively common complication among critically ill patients.
8. Treatment of acute hypophosphatemia usually requires intravenous supplementation of phosphorous salts.

Disorders of calcium and phosphorus are common complications of multiple acute and chronic diseases. These disorders are frequently seen in the acute care setting; however, they are also often present in ambulatory patients, usually in a less severe state. The consequences of electrolyte disorders can range from asymptomatic to life-threatening, requiring hospitalization and emergent treatment. The maintenance of fluid and electrolyte homeostasis requires adequate functioning and modulation by multiple hormones on tissues of multiple organ systems.

There are many common drug therapies that can disturb the normal homeostatic mechanisms that maintain calcium and phosphorous balance. In addition, with some drug therapies, toxicity is enhanced when underlying electrolyte disorders are present. Drug-induced disorders typically respond well to discontinuation of the offending agent(s); however, additional therapies are sometimes required to correct the disorder. This chapter reviews the etiology, classification, clinical presentation, and therapy for the most common disorders of calcium and phosphorus homeostasis.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

DISORDERS OF CALCIUM HOMEOSTASIS

The maintenance of physiologic calcium concentrations in the intracellular and extracellular spaces is vital for the preservation and function of cell membranes; propagation of neuromuscular activity; regulation of endocrine and exocrine secretory functions; blood coagulation cascade; platelet adhesion process; bone metabolism; muscle cell excitation/contraction coupling; and mediation of the electrophysiologic slow-channel response in cardiac and smooth-muscle tissue.

The disorders of calcium homeostasis are related to the calcium content of the extracellular fluid, which is tightly regulated and comprises less than 0.5% of the total body stores of calcium. Skeletal bone contains more than 99% of total body stores of calcium.[1] Extracellular fluid (ECF) calcium is moderately bound to plasma proteins (46%), primarily albumin.[2] Ionized or free calcium is the physiologically active form and is the fraction that is homeostatically regulated.[3] Extracellular calcium, however, is most commonly measured as the total serum calcium level, which includes both bound and unbound calcium.[2] The normal total calcium serum concentration range is 8.5 to 10.5 mg/dL (2.13–2.63 mmol/L).[3]

Proper assessment of total serum calcium concentrations includes measurement of the patient's serum albumin concentration. Hypoalbuminemia, which can be associated with many chronic disease states, is probably the most common cause of "laboratory hypocalcemia." Patients remain asymptomatic because the unbound or ionized fraction of serum calcium remains normal (normal range, 4.4–5.4 mg/dL [1.10–1.35 mmol/L]). A corrected total serum calcium (S_{ca}) concentration can be calculated based on the measured total serum calcium and the difference between a patient's measured albumin concentration and the normative value of 4 g/dL (40 g/L) by the following equations:

$$\text{Corrected } S_{ca}\ (\text{mg/dL}) = \text{measured } S_{ca}\ (\text{mg/dL}) + [0.8 \times (4.0\ \text{g/dL} - \text{measured albumin (g/dL)})]$$

Or

$$\text{Corrected } S_{ca}\ (\text{mmol/L}) = \text{measured } S_{ca}\ (\text{mmol/L}) + [0.02 \times (40\ \text{g/L} - \text{measured albumin (g/L)})]$$

The concentration of ionized calcium is closely regulated by the interactions of parathyroid hormone (PTH), phosphorus,

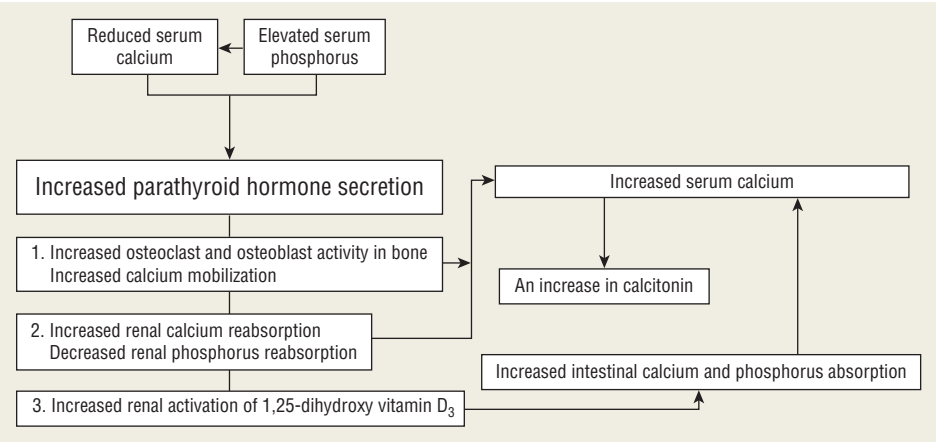

FIGURE 59-1. Homeostatic mechanisms to maintain serum calcium concentrations.

vitamin D, and calcitonin (Fig. 59–1). PTH increases serum calcium concentrations by stimulating calcium release from bone, increasing renal tubular reabsorption, and enhancing absorption in the gastrointestinal tract secondary to increased renal production of 1,25-dihydroxy vitamin D_3. Vitamin D directly increases serum calcium, as well as phosphorus concentrations, by increasing gastrointestinal absorption. Indirectly, it can also lead to calcium release from bone and reduced renal excretion. Calcitonin inhibits osteoclastic bone resorption. Its plasma concentrations are increased when ionized calcium concentrations are high as the body attempts to return the calcium level to the normal range. Disruption of these homeostatic mechanisms results in the clinical manifestations of hypercalcemia or hypocalcemia.

Alteration of the concentration of albumin or its binding of calcium can be expected to change the unbound fraction of total serum calcium. The most significant cause of changes in calcium binding to albumin is a change in extracellular fluid pH. In the presence of acute metabolic alkalosis the fraction of calcium bound to albumin is increased, thus reducing the plasma concentration of ionized calcium. This can result in symptomatic hypocalcemia; that is, paresthesia, muscle cramping and spasms, memory loss, and seizures.[1] Conversely, metabolic acidosis decreases calcium binding to albumin and results in increased ionized calcium. Hypoalbuminemic states are probably the most common cause of "laboratory hypocalcemia." When the albumin level is decreased, the ionized calcium concentration can be normal although total serum calcium concentration is low. Each 1 g/dL (10 g/L) drop in the serum albumin concentration below 4 g/dL (40 g/L) will result in a decrease of total serum calcium concentration by 0.8 mg/dL (0.20 mmol/L).[1,2] This approach of calculating an albumin-adjusted calcium concentration has been found to overestimate the degree of hypercalcemia and usually fails to identify hypocalcemia in critically ill patients, therefore ionized calcium values should be used to assess calcium status in these patients.[4,5]

HYPERCALCEMIA

There are multiple and diverse causes of hypercalcemia (total serum calcium >10.5 mg/dL [2.62 mmol/L]) (Table 59–1). The most common causes of hypercalcemia are cancer and primary hyperparathyroidism. The reported incidence of primary hyperparathyroidism in the United States ranges from 10 to 30 cases per 100,000 people.[6] Hypercalcemia of cancer occurs in approximately 20% to 40% of cancer patients at some time during the course of their disease.[7] Cancer-associated hypercalcemia is predominantly encountered in hospitalized patients, whereas primary hyperparathyroidism accounts for the vast majority of cases in the outpatient setting.[8,9]

PATHOPHYSIOLOGY

Hypercalcemia is the result of one or a combination of three primary mechanisms: increased bone resorption, increased gastrointestinal absorption, or increased tubular reabsorption by the kidneys (see Fig. 59–1).

Many tumors secrete PTH–related protein (PTHrP), which binds to the PTH receptors in bone and renal tissues, leading to increased bone resorption and renal tubular reabsorption.[10] Tumors can also secrete substances such as vitamin D, transforming growth factor, interleukins, prostaglandins, interferon, tumor necrosis factor, and granulocyte-macrophage colony–stimulating factor, which are associated with the development of hypercalcemia.[7] Hypercalcemia of malignancy is a common complication of squamous cell carcinomas of the lung, head, and neck, hematologic malignancies such as multiple myeloma and

TABLE 59-1 Etiologies of Hypercalcemia

Familial hypocalciuric hypercalcemia	
Adolescence	
Rhabdomyolysis	

T-cell lymphomas, and carcinomas of ovary, kidney, bladder, and breast. The most frequent types of malignancy associated with hypercalcemia are carcinomas of the lung and breast.[9] Breast and squamous cell lung carcinomas secrete PTHrP which binds to the type I PTH receptor (PTHR1) and enhances bone resorption. In contrast, up to 40% of patients with multiple myeloma develop hypercalcemia principally as the result of osteoclast-mediated bone destruction.[9]

Primary hyperparathyroidism is the most common cause of chronic hypercalcemia in the general population. Benign parathyroid adenomas account for 80% to 85% of these cases of hyperparathyroidism, parathyroid hyperplasia accounts for 15%, and parathyroid carcinoma is the cause in less than 1% of cases.[8]

Other causes of chronic hypercalcemia include medications, endocrine and granulomatous disorders, physical immobilization, high bone-turnover states (adolescence and Paget disease), and rhabdomyolysis. Increased gastrointestinal absorption can be the result of excessive ingestion of vitamin D analogs, calcium supplements, and lithium. Lithium and vitamin A therapy can increase bone resorption, whereas increased renal tubular reabsorption of calcium can occur with thiazide and lithium therapy. The exact mechanism of lithium-induced hypercalcemia is not known but may include competitive inhibition of calcium influx into cells, increasing the threshold sensitivity of the calcium-sensing receptor and subsequent inhibition of PTH gene transcription.[9] Addison's disease, acromegaly, and thyrotoxicosis are endocrine disorders that can lead to hypercalcemia because of increased renal tubular reabsorption and increased bone resorption. Finally, the granulomatous disorders (sarcoidosis, tuberculosis, histoplasmosis, and leprosy) are associated with hypercalcemia caused by an increase in gastrointestinal and renal tubular absorption secondary to granuloma production of 1,25-dihydroxy vitamin D_2.[12] Milk-alkali syndrome is the term applied to those situations where an individual develops hypercalcemia following the ingestion of calcium and absorbable alkali (e.g., calcium carbonate) and is an important cause of hypercalcemia in patients who are not on dialysis.[13,14]

CLINICAL PRESENTATION

Patients with mild to moderate hypercalcemia, that is, total serum calcium concentrations above the upper threshold of normal but less than 13 mg/dL (<3.25 mmol/L) or ionized calcium concentrations less than 6.0 mg/dL (<1.50 mmol/L), can often be asymptomatic. This is typically the case for the vast majority of patients who have drug-induced hypercalcemia or primary hyperparathyroidism.[8,15,16] In fact, one study noted normocalcemia in approximately 20% of patients with a diagnosis of primary hyperparathyroidism, suggesting target tissue resistance to PTH.[16]

1 The presenting signs and symptoms of severe hypercalcemia that occur if the total serum calcium concentration is >13 mg/dL (>3.25 mmol/L) may differ depending on the acuity of onset.[2] Hypercalcemia of malignancy usually develops quickly and is accompanied by a classic symptom complex of anorexia, nausea and vomiting, constipation, polyuria, polydipsia, and nocturia.[15] Polyuria and nocturia secondary to a urinary-concentrating defect constitute some of the most frequent renal effects of hypercalcemia.[15] Hypercalcemic crisis is characterized by an acute elevation of total serum calcium to a value >15 mg/dL (>3.75 mmol/L), acute renal insufficiency, and obtundation (inability to arouse).[15] If untreated, hypercalcemic crisis can progress to oliguric renal failure, coma, and life-threatening ventricular arrhythmias.[15] The primary complications associated with chronic hypercalcemia (hyperparathyroidism) include metastatic calcification, hypercalcuria, and chronic renal insufficiency secondary to interstitial nephrocalcinosis.[15]

CLINICAL PRESENTATION OF HYPERCALCEMIA

General

- The signs and symptoms of hypercalcemia depend on severity and on the rapidity of onset.

Symptoms

- Symptoms include fatigue, weakness, anorexia, depression, anxiety, cognitive dysfunction, vague abdominal pain, and constipation. Renal symptoms can include polyuria, polydipsia, and nocturia. Rarely, severe hypercalcemia leads to acute pancreatitis

Signs

- Renal: The most important renal manifestations which are generally the result of chronic hypercalcemia are nephrolithiasis; renal tubular dysfunction, particularly decreased concentrating ability; and acute and chronic renal insufficiency.
- Cardiovascular: Long-standing hypercalcemia can lead to the deposition of calcium in heart valves, coronary arteries, and myocardial fibers. Hypercalcemia also directly shortens the myocardial action potential, which is reflected in a shortened QT interval and coving of the ST-T wave. Spontaneous ventricular tachyarrhythmias and elevations in blood pressure have also been reported.
- Musculoskeletal: A number of rheumatologic complaints have been described in hyperparathyroidism, including gout, pseudo-gout, and chondrocalcinosis. The relative roles of hypercalcemia and PTH excess in these problems are not known.

Laboratory Tests

- Serum calcium concentrations of >10.5 mg/dL (>2.63 mmol/L) are considered to represent hypercalcemia. Patients with values up to 13 mg/dL (3.25 mmol/L) are generally considered to have mild or moderate hypercalcemia, whereas those with values greater than this indicate the presence of severe hypercalcemia.

Calcium and/or calcium-phosphorus complex deposition in blood vessels and multiple organs is a complication of chronic hypercalcemia and/or concomitant hyperphosphatemia and hyperparathyroidism. Calcium deposits in atherosclerotic lesions contribute to cardiac disease.[17] Intracardiac and arterial calcifications have been found in patients with Paget disease who have normal renal function. It is hypothesized that similar calcification processes occur in both bone and vascular tissue, leading to cardiovascular diseases including heart failure, systolic hypertension, and ischemic heart disease.[18]

The electrocardiographic changes associated with hypercalcemia include shortening of the QT interval and coving of the ST-T wave.[15] Very high serum calcium concentrations can cause T-wave widening, indicating a repolarization defect that may be associated with spontaneous ventricular tachyarrhythmias.[15] Hypertension and arrhythmias have occurred in the setting of hypercalcemia. The effects of digoxin on cardiac conduction including lowering of the excitation threshold, shortening of the effective refractory period and increased atrioventricular refractoriness, can be potentiated by hypercalcemia.[19]

Nephrolithiasis (kidney stones) and nephrocalcinosis (calcium deposits in the kidney) are the primary renal complications arising from long-standing hypercalcemia, as the result of primary hyperparathyroidism. Stone formation is dependent on

a favorable milieu within the kidney or urinary tract such as, oversaturation of the urine and/or reduced concentrations of endogenous inhibitors of crystal formation (e.g., citrate or pyrophosphate). It is estimated that hyperparathyroidism accounts for 2% to 8% of all patients with calcium stones.[20,21] Of note, in those patients with low glomerular filtration rates (GFRs), the 24-hour urinary calcium will actually diminish secondary to decreased production of 1,25-dihydroxy vitamin D_2. However, the fractional excretion of calcium might increase.[21] Sarcoidosis is the other hypercalcemic condition frequently associated with calcium stones.[20] Other causes of nephrolithiasis with calcium-containing stones include hypocitraturia, renal tubular acidosis, hyperoxaluria, and hyperuricosuria.[22,23] Stone formers who have primary hyper-parathyroidism are more likely to be female, older than 50 years of age, and have a family history of multiple endocrine disorders.[20] High dietary sodium intake can also raise urinary calcium concentrations, perhaps due to a reduction in calcium reabsorption in the kidney, thus predisposing patients to calcium stones. Although chronic renal failure can be the ultimate result of persistent stones, it is the primary cause of renal disease in <2% of the end-stage renal disease population.

TREATMENT

Hypercalcemia

DESIRED OUTCOME

The indications for the treatment of acute hypercalcemia are dependent on the severity of hypercalcemia, acuity of its development, and presence or absence of symptoms requiring emergent treatment (e.g., necrotizing pancreatitis). The therapeutic intervention plan should be crafted to reverse signs and symptoms, restore normocalcemia, and correct or manage the underlying cause of hypercalcemia.

Chronic hypercalcemia is usually caused by an underlying medical condition or prescribed pharmacotherapies that can be resolved by successful treatment of the condition or withdrawal of the offending agent. Acute hypercalcemic episodes induced by malignancies may be mitigated by chemotherapy and/or radiation treatment. Effective surgical or drug treatment of primary hyperparathyroidism should reduce serum calcium concentrations as well as reduce the development of long-term complications such as vascular complications, chronic kidney disease (CKD), and kidney stones.

NONPHARMACOLOGIC THERAPY

Hypercalcemic crisis and acute symptomatic severe hypercalcemia should be considered medical emergencies and treated immediately (Fig. 59–2).

These patients may require immediate-acting interventions to promptly reduce the serum calcium concentration if they are experiencing ECG changes, neurologic manifestations, or pancreatitis. Pharmacologic therapy consisting of volume expansion and enhancement of urinary calcium excretion with loop diuretics is usually the initial management strategy. Hemodialysis against a zero- or low-calcium dialysate solution should be considered for patients with severely impaired renal function (CKD stage 4 or 5) who cannot tolerate large fluid loads and in whom diuretics have limited efficacy.[22]

Effective treatment of moderate to severe hypercalcemia in the absence of life-threatening symptoms begins with attention to the underlying disorder and correction of associated fluid and electrolyte abnormalities. Patients with primary hyperparathyroidism may require surgery, particularly if they have systemic manifestations. Patients with malignancy often require surgical or chemotherapeutic reduction of tumor load to control the exogenous supply of cytokines and hormones (e.g. PTHrP) that cause hypercalcemia. In contrast, patients with drug-induced hypercalcemia generally respond to discontinuation of the offending agent.

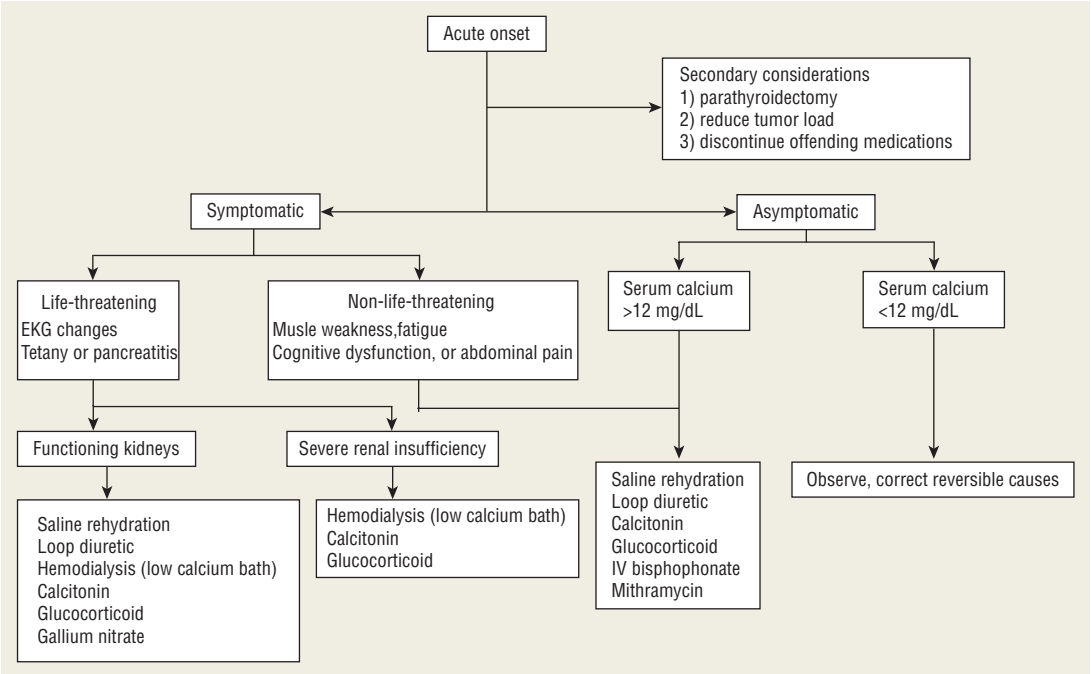

FIGURE 59-2. Pharmacotherapeutic options for the acutely hypercalcemic patient. Serum calcium of 12 mg/dL is equivalent to 3.00 mmol/L.

TABLE 59-2 Drug Therapy Used to Treat Acute Hypercalcemia

Drug	Starting Dosage	Time Frame to Initial Response	Contraindications	Adverse Effects
0.9% saline ± electrolytes	200–300 mL/hour	24–48 hours	Renal insufficiency; congestive heart failure	Electrolyte abnormalities; fluid overload
Loop diuretics	40–80 mg IV q 1–4 hours	N/A	Allergy to sulfas (use ethacrynic acid)	Electrolyte abnormalities
Calcitonin	4 units/kg q 12 hours SC/IM 10–12 units/hours IV	1–2 hours	Allergy to calcitonin	Facial flushing, nausea/vomiting, allergic reaction
Pamidronate	30–90 mg IV over 2–24 hours	2 days	Renal insufficiency	Fever
Etidronate	7.5 mg/kg/day IV over 2 hours	2 days	Renal insufficiency	Fever
Zoledronate	4–8 mg IV over 15 min	1–2 days	Renal insufficiency	Fever, fatigue, skeletal pain
Ibandronate	2–6 mg IV bolus	2 days	Renal insufficiency	Fever, musculoskeletal pain
Gallium nitrate	200 mg/m^2/day	?	Severe renal insufficiency	Nephrotoxicity; hypophosphatemia; nausea/vomiting/diarrhea; metallic taste
Mithramycin	25 mcg/kg IV over 4–6 hours	12 hours	Decreased liver function; renal insufficiency; thrombocytopenia	Nausea/vomiting; stomatitis; thrombocytopenia; nephrotoxicity; hepatotoxicity
Glucocorticoids	40–60 mg oral prednisone equivalents daily	3–5 days	Serious infections; hypersensitivity	Diabetes; osteoporosis; infection

SC, subcutaneous.

PHARMACOLOGIC THERAPY

CLINICAL CONTROVERSY

Although dialysis is the most effective method for rapidly reducing highly elevated serum calcium in patients with CKD, many clinicians choose normal saline and/or a loop diuretic approach as the initial therapy.

2 For those patients with normal to moderately impaired renal function (CKD stages 3 and 4), the cornerstone of initial treatment of severe hypercalcemia or hypercalcemic crisis is volume expansion with normal saline to increase natriuresis and ultimately urinary calcium excretion (see Table 59–2). Patients with symptomatic hypercalcemia are often extracellular volume depleted secondary to vomiting and polyuria; thus rehydration with saline-containing fluids is necessary to interrupt the stimulus for sodium and calcium reabsorption in the renal tubule.[24] Rehydration can be accomplished by the infusion of normal saline at rates of 200 to 300 mL/h, until the patient is fluid resuscitated and serum calcium approaches the upper limit of the normal range. The precise rate depends on concomitant conditions (primarily cardiovascular and renal) and magnitude of hypercalcemia. The saline infusion rate can be decreased to a rate that approximates the patient's intake of oral or intravenous fluids. (See Chapter 58 for a thorough discussion of the concepts and calculations of water deficit.) Adequacy of hydration is assessed by measuring fluid intake and output or by central venous pressure monitoring.[9] Loop diuretics such as furosemide (40–80 mg IV every 1–4 hours) or ethacrynic acid (for patients with sulfa allergies) can also be instituted to increase urinary calcium excretion and to minimize the development of volume overload from the administration of saline[9] (Fig. 59–2 and Table 59–2). Loop diuretics such as furosemide block calcium (and sodium) reabsorption in the thick ascending limb of the loop of Henle and augment the calciuric effect of saline alone. The importance of rehydration prior to loop diuretic use is critical because if dehydration persists or becomes worse the serum calcium can actually increase because of enhanced proximal tubule calcium reabsorption.[2] Potassium chloride, 10 to 20 mEq/L (10–20 mmol/L), should be added to the saline solution after rehydration is accomplished to maintain normokalemia in the presence of diuretic therapy. Serum magnesium levels should also be monitored, and magnesium replacement instituted if magnesium levels fall below 1.8 mg/dL (0.74 mmol/L). Rehydration with saline and administration of furosemide can result in a decrease of 2 to 3 mg/dL (0.50–0.75 mmol/L) in total serum calcium within 24 to 48 hours.[9]

In those patients in whom saline hydration therapy is contraindicated (e.g., those with severe chronic heart failure [CHF] or moderate to severe renal dysfunction), short-term therapy with calcitonin is a viable alternative agent to initiate reduction of serum calcium levels within 24 to 48 hours. Calcitonin has a rapid onset of action (within 1–2 hours); however, the degree and extent of serum calcium level reduction are often unpredictable.[2] Calcitonin decreases serum calcium concentrations, primarily by inhibiting bone resorption. It can also reduce renal tubular reabsorption of calcium, thus promoting calciuresis.[25] Recently, the calcitonin receptor has been shown to play an important role in calcium homeostasis, particularly in states of calcium stress (e.g., vitamin D toxicity).[25] Calcitonin from salmon sources is most commonly administered subcutaneously or intramuscularly (for larger volumes) in a starting dose of 4 units/kg every 12 hours. The side effects from intravenously administered calcitonin (facial flushing, nausea, and vomiting) limit patient acceptability. Allergic reactions, although rare, do occur; therefore a test dose (intradermal injection of 0.1 mL of a 10-units/mL solution) is recommended prior to starting therapy. If marked erythema and/or wheal formation does not occur within 15 minutes after administration, therapy can begin. Salmon calcitonin therapy is associated with tachyphylaxis caused by antibody formation to foreign proteins or molecules resembling the calcitonin polypeptide.[25] Tachyphylaxis has been primarily documented in patients receiving therapy for more than 4 months and thus might not be clinically significant in the acute care setting. The addition of corticosteroid therapy or conversion to human calcitonin increases effectiveness.[2]

Finally, intravenous phosphate was used historically to rapidly reduce ionized calcium concentrations through the formation of insoluble calcium-phosphate salts. However, intravenous phosphate is extremely hazardous because extraskeletal (e.g., intraluminal and intrarenal) precipitation of calcium-phosphate can result in metastatic calcification, hypotension, acute renal failure, or death and thus it currently does not have a role in the management of acute hypercalcemia.[2]

Bisphosphonates block bone resorption very efficiently, render the hydroxyapatite crystal of bone mineral resistant to hydrolysis by phosphatases, and also inhibit osteoclast precursors from attaching to the mineralized matrix, thus blocking their transformation into mature functioning osteoclasts.[15,26] The antiresorptive properties of this class of agents can provide long-term control of serum calcium and are the first-line therapy for cancer-associated hypercalcemia.

Pamidronate is very effective in controlling hypercalcemia associated with malignancy and slightly more effective than etidronate.[7] The usual dose of pamidronate is 30 to 90 mg as an IV infusion given over 2 to 24 hours. Pamidronate also has the advantage of single-day therapy.[9] Etidronate, when administered in doses of 7.5 mg/kg per day by slow intravenous infusion over at least 2 hours for 3 days, is effective in the therapy of hypercalcemia of malignancy.[9] Zoledronate and ibandronate are the newest high-potency bisphosphonates with demonstrated effectiveness in the treatment of hypercalcemia of malignancy. Complete response has been reported in 88.4% to 86.7% of zoledronate-versus 69.7% of pamidronate-treated patients.[27,28] Zoledronate intravenous doses of 4 to 8 mg given over 5 minutes have resulted in normalization of serum calcium concentrations.[28] Intravenous infusions of 0.02 or 0.04 mg/kg diluted in 5% dextrose (given over 20–50 minutes) have also been effective.[29] A similar hypocalcemic response has been noted with ibandronate in comparison with pamidronate (76.5% vs 75.8%); however, the time period to a relapse of hypercalcemia was longer with ibandronate (14 days vs 4 days), suggesting a therapeutic advantage for ibandronate.[30] In contrast to other bisphosphonates, ibandronate can be administered by bolus injection. Single doses of 4 to 6 mg when administered every 3 to 4 weeks have been effective in managing hypercalcemia of malignancy.[31] The onset of serum calcium concentration decline is slower with bisphosphonate therapy (concentrations begin to decline in 2 days and reach a nadir in 7 days); thus calcitonin therapy can be necessary if rapid serum level reduction is required.[9,31] Duration of normocalcemia varies, but usually does not exceed 2 to 3 weeks. It appears to be dependant on the severity and treatment response of the underlying malignancy.[2] The duration of response has been suggested to be longer with zoledronate (4–5 weeks), although the data is sparse.[29] Fever is a common side effect of intravenous bisphosphonate therapy. Although oral bisphosphonates are useful for the treatment of bone turnover in Paget disease, there are insufficient data to suggest their use for the initial treatment of hypercalcemia. The use of oral bisphosphonates for maintenance therapy in patients predisposed to hypercalcemia (malignancy) has been successful in some cases.[32] The safety of continuous bisphosphonate therapy in patients with moderate to severe renal insufficiency is currently unknown. Renal function monitoring (serum creatinine) is advised with the use of bisphosphonates, as cases of acute tubular necrosis have been reported.[33,34] Although there are no published guidelines for frequency of serum creatinine monitoring, it is advisable to evaluate serum creatinine within a week after the infusion and just prior to the next scheduled dose.

CLINICAL CONTROVERSY

Bisphosphonates are renally eliminated and prescribing information advises that they be used with caution in patients with a GFR less than 30 mL/min (<0.5 mL/s); however, many clinicians use these agents for first-line treatment of cancer-related hypercalcemia.

Gallium nitrate is indicated for the treatment of symptomatic hypercalcemia of malignancy not responsive to hydration therapy.[35] However, because of its adverse side-effect profile, it is generally reserved for those who fail to respond to less toxic agents. Gallium nitrate inhibits bone resorption, and may be superior to calcitonin in inducing normocalcemia. It can provide a longer duration of normocalcemia as compared with etidronate. The initial dose is usually a continuous IV infusion of 200 mg/m^2 per day for 5 consecutive days. Gallium nitrate can be more effective in achieving normocalcemia in patients with epidermoid (squamous) cancers.[36] Because gallium nitrate is nephrotoxic, the initial dose should be conservative and the patient's renal function closely monitored if it is coadministered with other nephrotoxic drugs, including some chemotherapeutic agents, nonsteroidal anti-inflammatory drugs (NSAIDs), and antibiotics (e.g., gentamicin). Other common adverse effects include hypophosphatemia, nausea, vomiting, diarrhea, hypocalcemia, and metallic taste.

Mithramycin (plicamycin) is a potent cytotoxic antibiotic that inhibits osteoclast-mediated bone resorption and thereby reduces hypercalcemia. Mithramycin can be administered at a dose of 25 mcg/kg via intravenous infusion over 4 to 6 hours in saline or 5% dextrose solutions. This therapy can be repeated daily for 3 to 4 days or on alternating days for 3 to 8 doses.[9,37] Serum calcium levels begin to fall within 12 hours of a mithramycin dose, with the peak effect generally occurring over 48 to 96 hours.[2,9] Single doses are usually well tolerated.[37] Common dose-related adverse effects of mithramycin include nausea, vomiting, stomatitis, thrombocytopenia, inhibition of platelet function, and renal and hepatotoxicity can be avoided by limiting the number of doses administered to less than four.[2] Mithramycin is usually limited to short-term therapy (typically one to two doses) in patients who have not responded to alternative therapies. Complete blood count, liver function, and renal function should be monitored within 1 to 2 days after administration. Mithramycin should be avoided in patients with thrombocytopenia and liver and renal insufficiency (creatinine clearance <30 mL/min [<0.5 mL/s]).[9]

Denosumab is a monoclonal antibody that inhibits the receptor activator of nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB) ligand (RANKL), a principal mediator of osteoclast survival. Denosumab is in phase III clinical trials for the treatment of osteoporosis. Recently, denosumab has been investigated in patients with malignancies and bone metastases (without hypocalcemia) who were either bisphosphonate naïve or who had previous exposure to bisphosphonates. Patients were randomized to receive an IV bisphosphonate every 4 weeks (91% received zoledronic acid) or a fixed dose of denosumab every 4 weeks (30, 120, 180 mg) or every 12 weeks (60, 180 mg) to investigate the effect on the primary outcome measure of urinary-N-telopeptide, a marker for bone turnover. Patients who were bisphosphonate naïve had similar decline in markers of bone turnover. In patients with previous exposure to bisphosphonates, treatment with denosumab produced significantly greater reductions in bone turnover compared with an IV bisphosphonate. These preliminary results indicate that denosumab reduces bone turn over and may be efficacious in preventing or treating hypercalcemia of malignancy.[38]

Prednisone or an equivalent agent in the corticosteroid class is usually effective in the treatment of hypercalcemia resulting from multiple myeloma, leukemia, lymphoma, sarcoidosis, and hypervitaminoses A and D.[2,26,37] These agents are effective because they reduce gastrointestinal calcium absorption and decrease renal tubular calcium reabsorption.[37] Corticosteroids may also prevent tachyphylaxis to salmon calcitonin.[25] Daily doses of 40 to 60 mg of prednisone or the equivalent are effective at reducing serum calcium within 3 to 5 days followed by a reduction in urinary calcium excretion within 7 to 10 days. The disadvantages of corticosteroid therapy are its relatively slow onset of action and the

TABLE 59-3 Treatment of Nephrolithiasis Associated with Chronic Hypercalcemia and Hypercalciuria

Intervention	Indications	Comments
Extracorporeal shock wave lithotripsy		
Uses sound waves to break up stones which then can pass spontaneously	Obstruction of the urinary tract especially with stones >5 mm	Consider adjunctive use of potassium citrate to inhibit aggregation of residual fragments
Prevention of Stone Formation		
Alkalinizing agents Potassium citrate PO 20 mEq twice daily Sodium citrate PO 20–30 mEq twice daily	Treatment for nonemergent active stones Can also be used for prevention	Potassium citrate preferred over sodium citrate as it decreases urinary calcium, inhibits calcium oxalate precipitation, and increases urinary citrate more
Decrease urinary calcium excretion		
Thiazide diuretics Hydrochlorothiazide PO 50 mg every day Indapamide PO 25 mg every day Chlorthalidone PO 25 mg every day	Prevention	Drug of choice in patients with low bone density
Binding intestinal calcium		
Cellulose sodium phosphate (Calcibind) Calcium binding ion-exchange resin that decreases gastrointestinal absorption of calcium: PO 5 g twice daily with oxalate restriction	Prevention for those with absorptive hypercalcuria	Alternative to thiazides if intolerant or ineffective, monitor bone density
Inhibition of crystal formation		
Phyllanthus nituri plant extract Inhibits calcium oxalate stone formation by incorporating glycosaminoglycans into the calculi: PO 2 g daily	Prevention, after shock wave lithotripsy	Commercial preparations with *P nituri* as the sole ingredient can be difficult to obtain
Low calcium diet		
Less than 400 mg per day	Prevention	Monitor bone density prior to and periodically during treatment, limit oxalate restriction, can increase hyperoxaluria, data suggest high calcium intake may actually be more beneficial

potential for diabetes mellitus, osteoporosis, and increased susceptibility to infection.[39]

Asymptomatic patients with mild hypercalcemia may be carefully observed, especially if treatment for the underlying condition (malignancy) is initiated. The calcimimetic agent cinacalcet HCl was recently approved for its calcium-lowering effect in the management of parathyroid carcinoma.[40,41] It binds to the calcium-sensing receptor, and increases the sensitivity for receptor activation by extracellular calcium. This results in reduced PTH and serum calcium concentrations.[40,41] Cinacalcet HCl administered at a starting dose of 30 mg orally twice daily has been used for the treatment of hypercalcemia secondary to parathyroid carcinoma. The dosage is titrated every 2 to 4 weeks in 30-mg increments until the desired serum calcium level is achieved. The maximum approved dosage is 90 mg 3 to 4 times daily. Patients should have serum calcium measured within 1 week after starting or increasing the dose of this agent.[42,43]

Subcutaneous administration of salmon calcitonin, 50 to 100 international units daily or 3 times weekly, has been used to manage mild hypercalcemia in patients with Paget disease.[44] The intranasal formulation of calcitonin has been used in doses of 200 to 400 international units daily; unfortunately, this has resulted in only mild decreases in serum calcium. The lack of significant efficacy of the synthetic intranasal formulation is the result of the lower potency and shorter duration of action as compared to salmon calcitonin. Patients who develop nephrolithiasis from hypercalciuria are most often treated with sodium citrate to prevent stone formation, thiazide diuretics to decrease urinary calcium excretion, or shock wave lithotripsy (Table 59–3).

HYPOCALCEMIA

3 Hypocalcemia occurs infrequently in the outpatient setting and is most common in elderly, malnourished patients and those who have received sodium phosphate as a bowel preparation agent. The incidence of hypocalcemia in intensive care unit patients ranges from 70% to 90% based on total serum calcium values less than 8.5 mg/dL (<2.13 mmol/L) to 15% to 50% based on the observation of ionized calcium concentrations less than 4.4 mg/dL (<1.10 mmol/L).[3] Emergent treatment of hypocalcemia is rarely warranted unless life-threatening symptoms are present (e.g., frank tetany or seizures).

PATHOPHYSIOLOGY

Hypocalcemia is the result of alterations in the effect of PTH and vitamin D on the bone, gut, and kidney (see Fig. 59–1). The primary causes of hypocalcemia are postoperative hypoparathyroidism and vitamin D deficiency. Other causes include magnesium deficiency, thyroid surgery, medications, hypoalbuminemia, blood transfusions, peripheral blood progenitor cell harvesting, tumor lysis syndrome, and mutations in the calcium-sensing receptor.[45–50] PTH concentrations are elevated in conditions of hypocalcemia, with the exception of hypoparathyroidism and hypomagnesemia.[51]

Vitamin D Deficiency

Vitamin D and its metabolites play an important role in the maintenance of extracellular calcium concentrations and in normal

skeletal structure and mineralization. Vitamin D is necessary for the optimal absorption of calcium and phosphorus. On a worldwide basis, the most common cause of chronic hypocalcemia is nutritional vitamin D deficiency. In malnourished populations, manifestations include rickets and osteomalacia. Nutritional vitamin D deficiency is uncommon in Western societies because of the fortification of milk with ergocalciferol. The most common cause of vitamin D deficiency in Western societies is gastrointestinal disease.[15] Gastric surgery, chronic pancreatitis, small-bowel disease, intestinal resection, and bypass surgery are associated with decreased concentrations of vitamin D and its metabolites.[15] Vitamin D replacement therapy might need to be administered by the intravenous route if poor oral bioavailability is noted. Decreased production of 1,25-dihydroxyvitamin D_3 can occur as a result of a hereditary defect resulting in vitamin D–dependent rickets. Recently, polymorphisms of the vitamin D receptor have been identified, and these genetic variations can contribute to increased risk of rickets associated with vitamin D and calcium deficient diets, especially in certain African and East Asian populations.[53] It also can occur secondary to chronic kidney disease if there is insufficient production of the 1-α-hydroxylase enzyme for the production of the most active metabolite, 1,25-dihydroxy vitamin D_3.[54] Treatment of hypocalcemia associated with CKD is reviewed in Chapter 53.

Hypomagnesemia

Hypomagnesemia of any cause can be associated with severe symptomatic hypocalcemia that is unresponsive to calcium replacement therapy (see Chapter 60). Reduced serum magnesium concentrations can impair PTH secretion and induce resistance of target organs to the actions of PTH.[15] Normalization of serum calcium concentrations in these patients is thus dependent on appropriate replacement of magnesium.

Tissue Consumption of Calcium

Decreased total serum calcium concentrations are seen in up to 10% of patients with acute pancreatitis, principally due to low serum albumin concentrations. These patients typically have more severe attacks, a poorer prognosis, and increased mortality rates.[55] The mechanisms responsible for the development of true hypocalcemia in pancreatitis have not been completely elucidated but may include binding of calcium to liberated fatty acids or possibly transcellular shifts induced by gram-negative endotoxin translocated from the gastrointestinal tract.[55] The etiology of sepsis-associated hypocalcemia may be the result of inflammatory mediators affecting calcium homeostasis.[56] Finally, rhabdomyolysis and tumor lysis syndrome can result in acute elevations of serum phosphorus that can bind ionized calcium.

Hungry Bone Sydrome

An acute, symptomatic rapid fall in total serum calcium concentration (to values <7 mg/dL [<1.75 mmol/L]) is common in patients who have recently had a parathyroidectomy or thyroidectomy. Hypocalcemia in these postsurgical patients is generally transient in nature.[52] The "hungry bone syndrome" is a condition of profound hypocalcemia whereby the bone avidly incorporates calcium and phosphorus from the blood in an attempt to recalcify bone. Serum calcium concentrations should be monitored every 6 hours during the 24 to 48 hours following such surgeries, and pharmacologic doses of calcium can be necessary to prevent or minimize the drop in serum calcium. Additionally, mild to moderate hypocalcemia can be a long-term consequence of parathyroidectomy in hemodialysis patients.[52]

Drug-Induced Hypocalcemia

Drug-induced hypocalcemia has been reported in patients receiving furosemide, calcitonin, bisphosphonates, gallium nitrate, mithramycin, cinacalcet, fluoride, ketoconazole, and pentamidine.[43,57] Oral phosphorus therapy, commonly used to treat patients with malabsorption syndromes caused by gastrointestinal diseases, can also result in hypocalcemia. The anticonvulsants phenobarbital and phenytoin cause hypocalcemia by increasing catabolism of vitamin D and thereby impairing calcium release from bone and reducing intestinal calcium absorption.[45] Drugs that cause hypomagnesemia (aminoglycosides, amphotericin B, cyclosporine, diuretics, foscarnet, and cisplatin) are also associated with an increased risk of hypocalcemia. Chelating agents in blood (citrate) and in radiographic contrast media (ethylenediamine tetraacetate) can also cause transient hypocalcemia.[45,46,58] Concentrated citrate is increasingly being used in hemodialysis catheter locks and to anticoagulate the dialysis circuit during continuous renal replacement therapy. Symptomatic hypocalcemia (ionized calcium <2.4 mg/dL [<0.60 mmol/L]) has been reported in patients exposed to citrate solutions, which appears to be related to the concentration of the citrate solution.[59] Injection of citrate solutions greater than the volume of the dead space of the catheter lumen or accidental injection of citrate catheter lock solutions that are not intended for systemic administration have been associated with serious cardiovascular problems such as hypotension or cardiac arrest.[60]

Hypoparathyroidism

Hypoparathyroidism can be caused by autoimmune disease, congenital defects, or iatrogenically by inadvertent removal during thyroidectomy or from damage with radiation therapy. Chronic hypothyroidism produces an insidious development of hypocalcemia and thus most patients remain asympotomatic. The chronic hypocalcemia may ultimately present as visual impairment secondary to cataracts.[61]

CLINICAL PRESENTATION

The clinical manifestations of hypocalcemia are quite variable. The more acute the drop in ionized calcium concentration, the more likely the patient will develop symptoms.[51] Increases in plasma pH enhances the binding of calcium to albumin thus alkalosis can result in rapid decreases in ionized calcium. Concomitant hypomagnesemia, hypokalemia, hyponatremia, and additive side effects from prescribed medications also increase the likelihood of symptomatic presentation.

Hypocalcemia can manifest as neuromuscular, CNS, dermatologic, and cardiac sequelae.[15] Acute hypocalcemia is more likely to manifest as neuromuscular (paresthesia, muscle cramps, tetany, and laryngeal spasm) and cardiovascular symptoms, whereas chronic hypocalcemia often presents as CNS (e.g., depression, anxiety, memory loss, confusion, hallucinations, and tonic-clonic seizures) and dermatologic symptoms (hair loss, grooved and brittle nails, and eczema).[45] The hallmark sign of acute hypocalcemia is tetany caused by enhanced peripheral neuromuscular irritability.[15] Tetany manifests as paresthesia around the mouth and in the extremities, muscle spasms and cramps, carpopedal (hands and feet) spasms, and rarely as laryngospasm and bronchospasm.[15] Chvostek's and/or Trousseau's signs can be elicited during physical examination.[45] Chvostek's sign is elicited by tapping the facial nerve anterior to the ear and eliciting twitching of facial muscles. Trousseau's sign is elicited by inflating a blood pressure cuff above systolic blood pressure for 3 minutes and observing whether a carpal spasm is induced.

The cardiovascular manifestations of hypocalcemia result in electrocardiographic changes characterized by a prolonged QT interval and symptoms of decreased myocardial contractility often associated with congestive heart failure.[45] Both acute and chronic hypocalcemia can result in a reversible syndrome characterized by acute myocardial failure or refractory congestive heart failure. Other cardiovascular manifestations include arrhythmias, bradycardia, and hypotension that are unresponsive to fluid and pressor administration.[45]

CLINICAL PRESENTATION OF HYPOCALCEMIA

General

- Hypocalcemia is caused in part by disorders of vitamin D or PTH. Acute causes of hypocalcemia result in rapid decreases in serum ionized calcium and can be associated with sepsis, alkalosis, or drugs. Parathyroidectomy or thyroidectomy are also associated with a rapid reduction in serum calcium. Vitamin D deficiency associated with malnutrition should not be overlooked as an etiology of chronic hypocalcemia.

Symptoms

- The symptoms of hypocalcemia, usually associated with an acute decrease in serum calcium, include tetany, paresthesia, muscle cramps, and laryngeal spasms. Chronic hypocalcemia is usually associated with the symptoms of depression, anxiety, memory loss, and confusion.

Signs

- Neurologic: The hallmark of acute hypocalcemia is tetany, which is characterized by neuromuscular irritability including seizure potential. Extrapyramidal disorders, mainly parkinsonism but also dystonia, hemiballismus, choreoathetosis, and oculogyric crises occur in 5% to 10% of patients with idiopathic hypoparathyroidism. Chvostek's and/or Trousseau's signs can be elicited during physical examination.
- Dermatologic: The skin can be dry, puffy, and coarse. Other dermatologic manifestations can include hyperpigmentation, dermatitis, eczema, and psoriasis. Hair and skin signs including coarse, brittle, and sparse hair with patchy alopecia and brittle nails can also appear.
- Ophthalmologic: Cataract development has been reported to occur with hypocalcemia.
- Dental manifestations: These are usually associated with the presence of chronic hypocalcemia in early development. Signs include dental hypoplasia, failure of tooth eruption, defective enamel and root formation, and abraded carious teeth.
- Cardiovascular: Hypotension, decreased myocardial performance, and congestive heart failure have been reported. A prolonged QT interval, arrhythmias, and bradycardia can also occur but are more common with acute or very severe hypocalcemia.
- Gastrointestinal: Steatorrhea can be associated with chronic hypocalcemia.
- Musculoskeletal: Although patients with chronic hypocalcemic disorders have skeletal abnormalities, such findings do not appear to be direct consequences of hypocalcemia. Some patients with hypocalcemia have myopathy.
- Endocrine: Hypocalcemia alone can impair insulin release. In addition, idiopathic hypoparathyroidism can be associated with polyglandular autoimmune syndromes.

Laboratory Tests

- Serum calcium levels of less than 8.5 mg/dL (<2.13 mmol/L) are considered to represent hypocalcemia if ionized calcium values are also less than 4.4 mg/dL (<1.1 mmol/L).

TREATMENT

Hypocalcemia

DESIRED OUTCOME

4 The goals of therapy for patients with normal renal function are the resolution of signs and symptoms of hypocalcemia, restoration of normocalcemia, management of associated electrolyte abnormalities, and treatment of the underlying cause of hypocalcemia. The goals for patients with chronic kidney disease are different and are discussed in detail in Chapter 53. Asymptomatic hypocalcemia associated with hypoalbuminemia requires no treatment because ionized (physiologically active) plasma calcium concentrations are normal. Treatment of hypocalcemia is dependent on identification of the pathogenesis of the underlying disorder, acuteness of onset, and presence and severity of symptoms. Acute symptomatic hypocalcemia requires parenteral administration of soluble calcium salts (Fig 59–3).

PHARMACOLOGIC THERAPY

The initial therapeutic intervention for patients with acute symptomatic hypocalcemia is to administer 100 to 300 mg of elemental calcium intravenously over 5 to 10 minutes.[62] This can be accomplished by the administration of 1 g of calcium chloride (27% elemental calcium) or 2 to 3 g of calcium gluconate (9% elemental calcium). Calcium gluconate is generally preferred over calcium chloride for peripheral venous administration because calcium gluconate is less irritating to veins. The use of calcium gluconate provides a less predictable and slightly smaller increase in plasma ionic calcium compared with calcium chloride. Calcium should not be infused at a rate greater than 60 mg of elemental calcium per minute because severe cardiac dysfunction, including ventricular fibrillation, can result.[62] Intravenous calcium administration should be used with caution in patients receiving digitalis glycosides because of the possibility of bradycardia or atrioventricular (A-V) block.[3] The bolus dose of calcium is only effective for 1 to 2 hours and should be followed by a continuous infusion of elemental calcium at a rate of 0.5 to 2 mg/kg per hour.[3] The calcium concentrations should be monitored every 4 to 6 hours during the intravenous infusions. The ionized calcium concentration usually normalizes within 4 hours, and the maintenance infusion rate of elemental calcium can then be decreased to 0.3 to 0.5 mg/kg per hour to maintain the desired calcium concentration.[1] Calcium should not be added to bicarbonate- or phosphate-containing solutions because of the possibility of precipitation.

Once acute hypocalcemia is corrected by parenteral administration, further treatment modalities should be individualized according to the cause of hypocalcemia. If hypomagnesemia is present, magnesium supplementation is indicated (see Chapter 60). Hypocalcemia secondary to hungry bone syndrome following parathyroidectomy has been attenuated by pretreatment with bisphosphonates.[63] Asymptomatic and chronic hypocalcemia associated with hypoparathyroidism and vitamin D–deficient states can be managed by oral calcium and vitamin D supplementation (see Chapter 53). Therapy is begun with 1 to 3 g/day of elemental calcium.[1] Average maintenance doses range

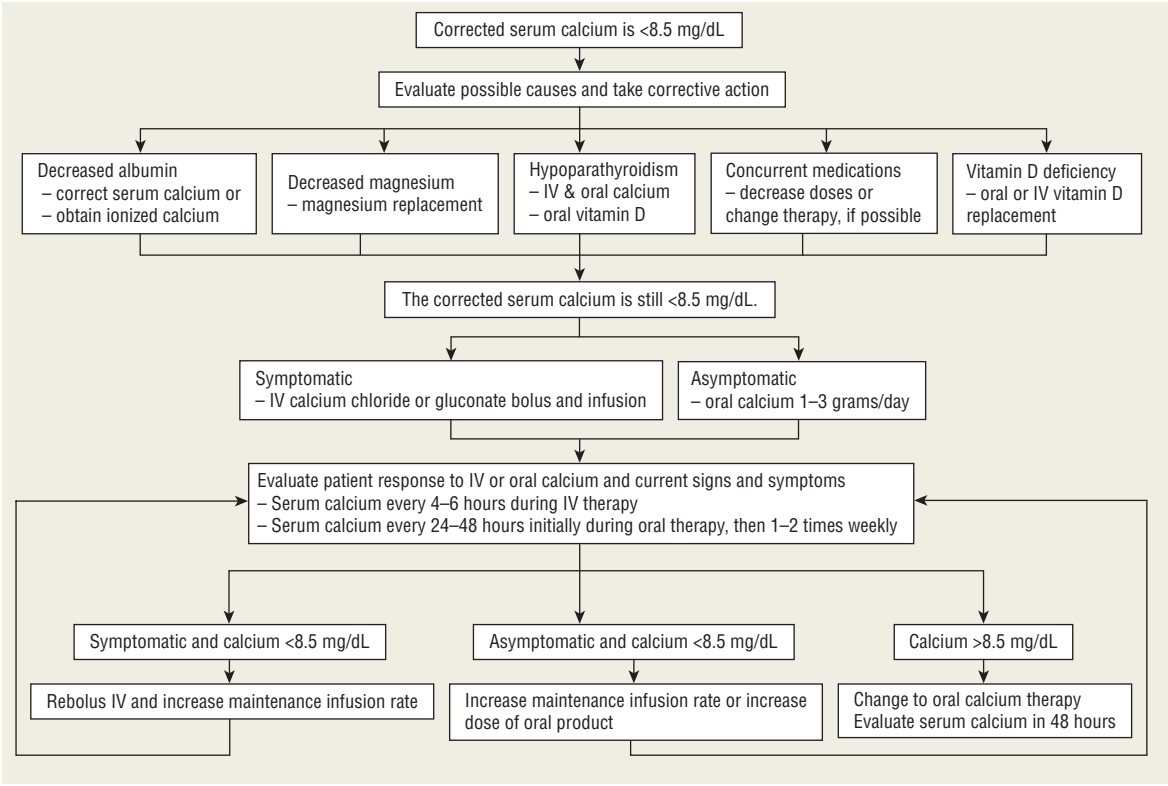

FIGURE 59-3. Hypocalcemia diagnostic and treatment algorithm. Serum calcium of 8.5 mg/dL is equivalent to 2.13 mmol/L.

from 2 to 8 g of elemental calcium per day in divided doses. If serum calcium does not normalize, a vitamin D preparation may need to be added.

Treatment of hypocalcemia associated with vitamin D–deficient states should be individualized. In patients with malabsorption, vitamin D requirements vary markedly, and large doses can be required. In contrast, vitamin D deficiency associated with anticonvulsant medication can be corrected with smaller doses of vitamin D. Oral doses of 1,25-dihydroxy vitamin D_3 usually range from 0.5 to 3 mcg daily. The usual initial oral dose of ergocalciferol is 50,000 international units daily.[62] Vitamin D doses are usually adjusted approximately every 4 weeks. Vitamin D deficiency is highly prevalent especially in areas of low sun exposure and limited dietary sources of vitamin D.[64] New data suggest that current dietary recommendations are not sufficient to maintain 25-hydroxy vitamin D_3 concentrations at or above 32 mcg/L (90 mmol/L).[64] The treatment of vitamin D deficiency associated with CKD generally requires the administration of 1,25-dihydroxy vitamin D_3 or another synthetic vitamin D_2 analog such as paricalcitol or doxercalciferol. Patients who have reduced 25-hydroxylase activity (e.g., hepatic disease) can also require treatment with calcitriol (1,25-dihydroxy vitamin D_3). The newer vitamin D_2 analogs (paricalcitol and doxercalciferol) were developed to preferentially suppress PTH secretion with less effect on serum calcium concentration and thus their efficacy for the management of hypocalcemia may be minimal. In selected cases, increasing calcium ingestion can be required if vitamin D replacement alone is ineffective in returning calcium concentrations to normal.

Adverse effects of oral calcium and vitamin D supplementation include hypercalcemia and hypercalciuria, especially in the hypoparathyroid patient, in whom the renal calcium-sparing effect of PTH is absent. Hypercalciuria can increase the risk of calcium stone formation and nephrolithiasis in susceptible patients. One maneuver to help prevent calcium stones is to maintain the urine calcium excretion below 300 mg per day. Intermittently monitoring 24-hour urine collections for total calcium excretion can help to minimize the occurrence of hypercalciuria. The addition of thiazide diuretics for patients at risk for stone formation can result in an increase in tubular calcium reabsorption and reduction of vitamin D requirements.[62]

DISORDERS OF PHOSPHORUS HOMEOSTASIS

Inorganic phosphorus in the form of phosphate is an essential element in phospholipid cell membranes, nucleic acids, and phosphoproteins, which are required for mitochondrial function.[65] Phosphorus regulates the intermediary metabolism of carbohydrates, fats, and proteins. Phosphorus also regulates enzymatic reactions including glycolysis, ammoniagenesis, and the 1-hydroxylation of 25-hydroxy vitamin D_3.[65] In addition, phosphorus is required for the generation of 2,3-diphosphoglycerate (2,3-DPG) in red blood cells, which is required for normal oxygen-hemoglobin dissociation and delivery of oxygen to the tissues.[66] Phosphorus is the source of the high-energy bonds of adenosine triphosphate (ATP), thus fueling a wide variety of physiologic processes, including muscle contractility, electrolyte transport, neurologic function, and other important biochemical reactions.[65] Considering its diverse biologic importance, it is not difficult to appreciate the clinical implications of disorders of phosphorus homeostasis.

Phosphate, the major intracellular anion, is present in living organisms mainly as organic phosphate esters such as 2,3-DPG, adenosine, guanosine triphosphate, and fructose 1,6-diphosphate.[65] Only a small fraction of intracellular phosphorus exists as inorganic phosphate; however, this fraction is critical because it is the source from which ATP is resynthesized.[65] The majority of inorganic phosphate is located in the extracellular space where it is the prime determinant of intracellular phosphate; thus, small increments in

the organic phosphate levels can profoundly alter both the extracellular and intracellular phosphate levels. Metabolic disturbances (acidosis, alkalosis, and ketoacidosis), hydrogen ion shifts, and hormones (PTH, calcitonin, cortisol, and vitamin D) all can cause transcellular shifts in phosphorus concentrations. Because of these phenomena, the serum phosphorus level does not accurately reflect total body stores.[66]

The typical Western diet provides a daily intake of 800 to 1,600 mg of phosphorus. Approximately 60% to 80% of this is absorbed in the gastrointestinal tract by passive and active transport (vitamin D mediated). PTH, 1,25-dihydroxy vitamin D_3, and low-phosphate diets mediate increased absorption. Decreased absorption occurs under conditions of increased dietary intake of phosphorus and magnesium, glucocorticoid therapy, and hypothyroidism. The normal serum phosphorus concentration in adults is 2.5 to 4.5 mg/dL (0.81–1.45 mmol/L) and for children younger than 12 years old it is 4 to 5.6 mg/dL (1.29–1.81 mmol/L). Influx via the gastrointestinal tract and bone and tubular reabsorption by the kidney are the most important regulators of steady-state serum phosphorus concentrations. Renal excretion of phosphorus is a two-step process: glomerular filtration and proximal tubular reabsorption by passive transport coupled to sodium. Under normal conditions, 85% to 90% of filtered phosphate is reabsorbed, the majority in the early proximal tubule. Renal tubular reabsorption of phosphate is inhibited by PTH and 1,25-dihydroxy vitamin D_3.[65] There are increasing data in the literature that indicate fibroblast growth factor 23 (FGF23) is a key regulator of phosphate homeostasis.[68,69] FGF23 acts principally to decrease tubular reabsorption of phosphate and inhibit 1α-hydroxylase, thereby reducing the concentration of active vitamin D. FGF23-mediated receptor activation requires klotho, a transmembrane protein. The tissue specificity for FGF23 effects appears to be defined by klotho-FGF23 coexpression. Conversely, phosphate reabsorption in the renal tubule is increased by growth hormone, insulin and insulin-like growth factor 1.[65] Internal phosphorus balance (transcellular phosphate distribution) is also of importance in the maintenance of normal serum phosphate. The serum phosphate level can vary by as much as 2 mg/dL (0.65 mmol/L) throughout the day, primarily as the result of changes in carbohydrate intake, insulin secretion, and diurnal variation.[65]

HYPERPHOSPHATEMIA

Hyperphosphatemia typically results from either renal failure or endogenous intracellular phosphate release. Hyperphosphatemia occurs frequently in patients with acute renal failure and is a nearly universal finding in those with advanced stages of CKD (e.g., stages 4 and 5). Tumor lysis syndrome is a complication of chemotherapy associated with massive lysis of cells and release of intracellular contents. The incidence of tumor lysis syndrome has been reported to be as high as 40% in patients treated for non-Hodgkin lymphoma.[65] Other causes of hyperphosphatemia include hemolysis and rhabdomyolysis.

Pathophysiology

5 The most common cause of hyperphosphatemia is a failure of renal tubular reabsorption to maintain serum phosphate when GFR is markedly inpaired (e.g., GFR <25 mL/min [<0.42 mL/s]).[65] Retention of phosphate decreases vitamin D synthesis and induces hypocalcemia, which leads to an increase in PTH, a finding that can be seen in those with stage 2 to 3 CKD. This physiologic response inhibits further tubular reabsorption of phosphorus as the kidney attempts to correct hyperphosphatemia and normalize serum calcium concentrations. Patients with excessive exogenous phosphate administration or who experience massive tissue breakdown or cell lysis in the setting of acute renal failure can rapidly develop moderate to severe hyper-phosphatemia (serum phosphate >6.5 mg/dL [>2.10 mmol/L]).[65] Severe hyperphosphatemia (serum phosphate >7.0 mg/dL [>2.26 mmol/L]) is commonly encountered in patients with CKD, especially those with GFRs less than 15 mL/min per 1.73 m^2 (0.14 mL/min/m^2) (see Chapter 53).

Hyperphosphatemia caused by an increase in renal tubular reabsorption associated with hypoparathyroidism and associated decreases in PTH is usually less severe than that observed in patients with severe renal failure or excessive exogenous or endogenous introduction of phosphate into the ECF. Acromegaly (mediated by growth hormone) and thyrotoxicosis (mediated by catecholamines) can also cause hyperphosphatemia by increasing tubular phosphate reabsorption.

Exogenous Phosphate Loads

Iatrogenic causes of hyperphosphatemia have been widely reported, and clinicians should be aware of the phosphorus content of intravenous, oral, and rectally administered products. Large doses of phosphate administered intravenously to treat hypercalcemia can ultimately result in severe life-threatening hyperphosphatemia. Although less-well recognized, oral and rectal administration of phosphate-containing solutions such as sodium phosphate (Fleet Phospho-Soda) can also result in severe and life-threatening hyperphosphatemia, especially in patients with moderate and severe renal insufficiency.[67,70] The risk of mortality is dependent on the amount of phosphorus absorbed from the administered product, however, fatalities have occurred at lower phosphate concentrations.[67] Acute phosphate nephropathy and renal failure have also been reported with the use of oral sodium phosphate bowel preparations. Recently the FDA issued a safety warning regarding the use of these products in patients at risk (the elderly, those with CKD) or on medications known to effect renal hemodynamics (e.g., diuretics, NSAIDs or renin-angiotensin-aldosterone system inhibitors).[71] Intravenous or oral vitamin D therapy can increase absorption of phosphorus in the gastrointestinal tract by up to 50%. High-dose etidronate (10–20 mg/kg/d) therapy has been associated with increased serum phosphate concentrations apparently mediated by drug-related increase in tubular phosphate reabsorption.[72] Acute phosphorus poisoning as a result of ingestion of laundry detergents is a rare and often unrecognized cause of elevated phosphate concentrations.

Rapid Tissue Catabolism

Any disorder that results in necrosis of skeletal muscle (i.e., rhabdomyolysis) can generate the release of large amounts of intracellular phosphate into the systemic circulation. This condition is frequently associated with acute kidney injury (see Chapter 51) and thus severe hyperphosphatemia can develop because of increased endogenous phosphate release coupled with the impaired proximal tubule reabsorption such that phosphaturic hormones (e.g., PTH, FGF23) become ineffective. Bowel infarction, malignant hyperthermia, and severe hemolysis are also conditions that can increase endogenous release of phosphate.

Moderate hyperphosphatemia is also commonly observed in patients undergoing treatment for acute leukemia and lymphomas.[73] Chemotherapeutic treatment of acute lymphoblastic leukemia can result in the release of large amounts of phosphate into the systemic circulation secondary to lysis of lymphoblasts. Initiation of chemotherapy for Burkitt lymphoma results in tumor lysis syndrome, a rapid lysis of malignant cells that results in hyperphosphatemia, hyperuricemia, hyperkalemia, and hypocalcemia.[73]

Acid–Base Disorders

Lactic acidosis and diabetic ketoacidosis can trigger the transcellular shift of endogenous intracellular phosphate into the extracellular space and thereby dramatically increases serum

phosphorous concentrations. In one study, hyperphosphatemia was present in more than 90% of patients with diabetic ketoacidosis prior to the initiation of treatment.[74] After the institution of treatment, serum phosphate levels should be checked hourly as they can decrease rapidly, and patients can ultimately develop hypophosphatemia.

Clinical Presentation

The severe acute onset of hyperphosphatemia can result in calcium and phosphate complexation and lead to the precipitation of calcium phosphate into soft tissues, intrarenal calcification, nephrolithiasis, or obstructive uropathy. Other symptoms associated with moderate to severe hyperphosphatemia include nausea, vomiting, diarrhea, lethargy, and seizures. The major effects of long-term hyperphosphatemia are related to the development of hypocalcemia (caused by phosphate inhibition of renal 1-α-hydroxylase) and its related consequences, as well as vascular and organ damage resulting from the deposition of calcium-phosphate crystals. Extravascular calcification can result in band keratopathy, "red eye," pruritus, and periarticular calcification, especially in CKD patients. In addition, soft-tissue calcifications in the conjunctiva, skin, heart, cornea, lung, gastric mucosa, and kidney have been observed, primarily in CKD patients with chronic disordered mineral metabolism.[64] Hyperphosphatemia associated with CKD can result in renal osteodystrophy because of overproduction of PTH. This condition is discussed in detail in Chapter 53.

CLINICAL PRESENTATION OF HYPERPHOSPHATEMIA

General

- As the serum phosphate concentration is primarily determined by the ability of the kidneys to reabsorb phosphate, hyperphosphatemia is uncommon in patients with normal kidney function.

Symptoms

- Acute symptoms include GI disturbances, lethargy, obstruction of the urinary tract, and rarely seizures. Symptoms associated with chronic hyperphosphatemia are associated with deposition of calcium-phosphate crystals and include "red eye" and pruritus.

Signs

- The elevated calcium-phosphate product results in precipitation in arteries, joints, soft tissues, and the viscera. This can result in tissue necrosis, termed *calciphylaxis*.

Laboratory Tests

- Serum phosphate levels >4.5 mg/dL (>1.45 mmol/L) represent hyperphosphatemia.

TREATMENT

Hyperphosphatemia

DESIRED OUTCOME

Management of patients with acutely elevated serum phosphate should be directed at avoiding gastrointestinal and neurologic symptoms and preventing deposition in the urinary tract to avoid the development of acute renal failure. The treatment of hyperphosphatemia is focused on returning serum phosphate concentrations to the normal or near normal (for those with CKD) range, with the hope that one can minimize the long-term cardiovascular consequences of calcium-phosphate crystal deposition in the vasculature. Calcium-phosphate crystals are likely to form in vivo when the product of the serum calcium and phosphate concentrations exceeds 50 to 60 mg^2/dL^2 (4.0–4.8 $mmol^2/L^2$). The National Kidney Foundation's Dialysis Outcomes Quality Initiative guidelines for bone metabolism and disease defines the goal calcium-phosphorus product as less than 55 mg^2/dL^2 (4.4 $mmol^2/L^2$).[68] Furthermore, serum phosphate concentrations greater than 6.5 mg/dL (2.10 mmol/L) have been independently associated with increased morbidity and mortality.[75] Serum phosphate concentrations should be maintained in the 2.7 to 4.6 mg/dL (0.87–1.49 mmol/L) range for those with stages 3 and 4 CKD, whereas for patients in stage 5 CKD the goal is to maintain values between 3.5 and 5.5 mg/dL (1.13–1.78 mmol/L).[76]

PHARMACOLOGIC THERAPY

Severe symptomatic hyperphosphatemia manifesting as hypocalcemia and tetany should be treated by the intravenous administration of calcium salts. Although this can seem counterintuitive in a patient with a phosphate of 16 mg/dL (5.17 mmol/L) and a calcium of 7 mg/dL (1.75 mmol/L) (the calcium-phosphorus product is 112 mg^2/dL^2 [9.0 $mmol^2/L^2$]), correction of severe hypocalcemia is of primary importance because of the critical nature of this disorder. If calcium concentrations are not critically low, the initial management strategy should include limitation of all exogenous sources of phosphate and efforts to block further absorption should be initiated. Dialysis can be initiated if the patient remains symptomatic despite these interventions.

6 In general, the most effective way to treat nonemergent hyperphosphatemia is to decrease phosphate absorption from the GI tract by the use of phosphate-binding agents.[65] Antacids containing divalent and trivalent cations (calcium, lanthanum, magnesium, and aluminum), or sevelamer are the agents most frequently used in the prevention and treatment of hyperphosphatemia (see Table 53–8).[77,78] Long-term treatment with aluminum hydroxide and aluminum carbonate should be discouraged because the use of these agents has been associated with anemia, CNS disorders, and bone disease.[79] Short-term therapy with these agents is effective and safe. Aluminum and calcium are available in oral suspension formulations, which can aid administration in acutely ill patients with G-tubes. The most frequent adverse effect from phosphate-binding agents (especially calcium) is constipation (see Table 53–8). Calcium salts are the preferred phosphate-binding agents except when there is concomitant hypercalcemia. Therapy with the polymer agent (sevelamer) or lanthanum carbonate might avoid the detrimental effects associated with aluminum, magnesium, or calcium therapy.

CLINICAL CONTROVERSY

Emerging data suggest that noncalcium, nonaluminum phosphate binders can slow progression of cardiac calcification in chronic hemodialysis patients; however, there are no data to suggest that there are any benefits to using sevelamer for the management of those who develop acute hyperphosphatemia. Thus, a more cost-effective approach to phosphate binding in acute situations would be use of calcium- or aluminum-based binders.

HYPOPHOSPHATEMIA

Mild to moderate hypophosphatemia is typically found in patients with serum phosphate concentrations of 1 to 2 mg/dL (0.32–0.65 mmol/L), whereas severe hypophosphatemia that is

frequenly symptomatic is correlated with a phosphorus concentration of less than 1 mg/dL (0.32 mmol/L).[66] Hypophosphatemia has been observed in approximately 1% to 3% of the laboratory screening panels of patients who have been admitted to a hospital.[66] The incidence in hospitalized critically ill patients is 18% to 28%.[81] Unlike its severe form, mild or moderate hypophosphatemia seldom causes recognizable signs and symptoms.[73]

PATHOPHYSIOLOGY

7 Hypophosphatemia can be the result of decreased gastrointestinal absorption, reduced tubular reabsorption, or extracellular to intracellular redistribution.[65] Although mild to moderate hypophosphatemia is common and can occur in inpatients and outpatients, severe hypophosphatemia is predominantly encountered in the acute care setting and can be associated with life-threatening symptoms, including seizures, coma, and rhabdomyolysis (Table 59–4).

Phosphate-binding substances such as sucralfate, calcium carbonate, sevelamer, lanthanum carbonate, and aluminum- or magnesium-containing antacids have the potential to bind large amounts of phosphorus in the gut, thereby preventing absorption. If phosphate-binding agents are ingested on a chronic basis in conjunction with a dietary phosphorus deficiency, hypophosphatemia can result.[73] Patients who are receiving long-term phosphate-binding agents, those with peptic ulcer disease or CKD, and those who may be predisposed to moderate hypophosphatemia (alcoholics) are at highest risk for the development of severe hypophosphatemia. Hyperparathyroidism can cause hypophosphatemia as a result of decreased gastrointestinal absorption of dietary phosphorus.

TABLE 59-4 Conditions Associated with the Development of Hypophosphatemia

Decreased gastrointestinal absorption
Phosphate-binding drugs
Sucralfate
Calcium carbonate
Aluminum/magnesium antacids
Sevelamer
Lanthanum carbonate
Decreased dietary phosphorus intake
Glucocorticoids
Vitamin D deficiency/resistance
Hypoparathyroidism
Chronic diarrhea
Steatorrhea
Reduced tubular reabsorption
Hyperparathyroidism (primary and secondary)
Elevated FGF23
Recovery from burns
Rickets
Malignant neoplasms
Fanconi syndrome
Acute volume expansion
Metabolic acidosis
Renal transplantation
Vitamin D deficiency and/or resistance
Diuretics
Acetazolamide
Osmotic agents
Glucocorticoids
Sodium bicarbonate
Internal redistribution
Refeeding syndrome
Parenteral nutrition
Parathyroidectomy (hungry bone syndrome)
Alcoholism
Respiratory alkalosis
Diabetic ketoacidosis (correction)
Dextrose solutions
Insulin
Catecholamines
Anabolic steroids
Glucagon
Calcitonin
Erythropoietin

Reduced tubular reabsorption of phosphate can occur in hyperparathyroid (primary and secondary) patients with normal renal function and those with vitamin D deficiency or elevated FGF23 concentrations. Elevated PTH levels lead to an increase in serum calcium concentrations and decreased serum phosphate concentrations. Serum phosphorus is decreased as the result of a reduction in renal tubular reabsorption.[82] Recovery from extensive third degree burns is associated with development of an anabolic state as stress levels decrease and nutritional therapies take effect as well as a marked diuretic phase associated with an impressive renal loss of phosphate.[82] Because phosphate is rapidly incorporated into the new cells, this can contribute to the severity of the hypophosphatemia. Drugs that cause increased renal elimination of phosphate include diuretics (acetazolamide and osmotic diuretics), glucocorticoids, and sodium bicarbonate.

Rapid refeeding of malnourished patients with high-carbohydrate, high-calorie diets with inadequate amounts of supplemental phosphate can result in severe symptomatic hypophosphatemia. This phenomenon is especially prevalent in patients with other underlying risk factors for the development of hypophosphatemia, such as alcoholism.[82] The etiology of severe hypophosphatemia associated with hyperalimentation and nutritional recovery can be separated into two phases: acute, rapid hypophosphatemia secondary to intracellular shifts of phosphate resulting from glucose-induced insulin secretion; and the gradual decrease in serum phosphate concentration over 5 to 10 days secondary to tissue repair in the presence of phosphate deprivation.[83] The development of severe hypophosphatemia secondary to hyperalimentation can be prevented by the administration of 12 to 15 mmol of phosphate per liter of hyperalimentation solution or 15 mmol per 1,000 calories (4.2 kJ) of dextrose.[83] Transcellular shifts in phosphate also occur after parathyroidectomy, causing severe hypocalcemia and hypophosphatemia because of hungry bone syndrome (deposition of phosphate and calcium in the bone).

Severe and prolonged respiratory alkalosis (a result of hyperventilation, pain, anxiety, and sepsis) can cause hypophosphatemia.[66] Respiratory alkalosis is thought to contribute significantly to the hypophosphatemia observed during alcohol withdrawal.[66] Although patients with diabetic ketoacidosis may present with hyperphosphatemia, the institution of therapy to correct it can cause serum phosphate concentrations to decrease rapidly as phosphate shifts back into the intracellular compartment. In addition, the acidosis associated with the diabetic ketoacidotic state can cause a decomposition of organic compounds inside the cell and a release of inorganic phosphate into the plasma and subsequently into the urine.[65] The combination of intracellular phosphate breakdown and the shift of phosphate into cells on initiation of treatment can lead to severe hypophosphatemia. Drugs associated with transcellular shifts in phosphate include dextrose solutions, glucagon, insulin, catecholamines, calcitonin, erythropoietic agents, and anabolic steroids.

Chronic ethanol abusers are prone to a variety of serum electrolyte disorders including hypocalcemia, hypomagnesemia, hypokalemia, and hypophosphatemia. The etiology of hypophosphatemia in the alcoholic patient is multifactorial. Malnutrition, poor dietary

intake, diarrhea, vomiting, and the use of phosphate-binding antacids can all contribute to the hypophosphatemia of alcoholism.[65] In addition, serum phosphate concentrations may decrease after hospitalization in the alcoholic patient with the institution of dextrose-containing intravenous fluids as a result of an intracellular shift of phosphate.[65,83] Hyperventilation associated with the alcohol withdrawal syndrome can also contribute to the development of hypophosphatemia.[73,83] Alcoholic patients are particularly susceptible to the complications of hypophosphatemia such as rhabdomyolysis, which is often seen during withdrawal or refeeding.[73,83] Thus, serum phosphate concentrations should be routinely monitored in alcoholic patients.

CLINICAL PRESENTATION

The clinical manifestations of severe hypophosphatemia are diverse and many organ systems can be affected. It is likely that two primary biochemical abnormalities are responsible for most of the clinical manifestations of severe hypophosphatemia.[65] First, intracellular energy stores may be decreased secondary to depletion of intracellular ATP. This can result in disruptions in cellular function. Second, reduced red blood cell 2,3-DPG concentrations are associated with a shift to the left of the oxyhemoglobin saturation curve. This shift is associated with a decrease in the release of oxygen to peripheral tissues (increased oxygen affinity for hemoglobin) and may result in tissue hypoxia.[65] These metabolic disorders can be seen in a wide variety of organ systems.

Neurologic (CNS) manifestations of severe hypophosphatemia result in a metabolic encephalopathy syndrome. This progressive syndrome of irritability, apprehension, weakness, numbness, paresthesia, dysarthria, confusion, obtundation, seizures, and coma has been described in patients with severe hypophosphatemia.[73,82] Neuropsychiatric disturbances include apathy, delirium, hallucinations, and paranoia. Peripheral neuropathy and symptoms resembling Guillain-Barré syndrome have also been reported.[73]

Severe hypophosphatemia can result in significant dysfunction of skeletal muscle ranging from myalgia, bone pain, and weakness, with chronic hypophosphatemia, to potentially fatal rhabdomyolysis with severe acute hypophosphatemia.[82] Laboratory evaluations can help to distinguish between chronic and acute on chronic hypophosphatemia. Elevated alkaline phosphatase, normal creatine phosphokinase, and normal to low phosphate and calcium are present in cases of chronic hypophosphatemia. In contrast, hyperkalemia, hyperuricemia, elevated blood urea nitrogen and creatinine, hypercalcemia, and myoglobinuria are often present in cases in which rhabdomyolysis complicates the acute or chronic hypophosphatemia.[82] Hypophosphatemia can result in acute respiratory failure secondary to respiratory muscle weakness and diaphragmatic contractile dysfunction. Thus frequent assessment of serum phosphate concentration is indicated in patients at risk for respiratory failure. Likewise, adequate treatment of hypophosphatemia in respiratory failure can aid in successful weaning from the ventilator.[66] Dysphagia and ileus have also been attributed to hypophosphatemia.[66]

Myocardial dysfunction has been reported to be impaired in the setting of hypophosphatemia and has resulted in congestive cardiomyopathy. This has been reported in alcoholics, and postoperative and intensive care patients. A depletion in cardiac ATP stores has been hypothesized as the cause of this syndrome.[82] Arrhythmias have also been reported in patients with hypophosphatemia. Because hypophosphatemia is a potentially reversible cause of heart failure, it should be considered in patients who experience an acute deterioration in ventricular function.

Hematologic manifestations of hypophosphatemia include decreased levels of 2,3-DPG, decreased red blood cell ATP, and membrane rigidity.[65] When red blood cell ATP decreases to below 15% of normal, cells become spherocytic and rigid, and are trapped and destroyed in the spleen.[65] Therefore, hemolysis can be a manifestation of severe hypophosphatemia. Reduction in ATP content of white blood cells can result in mobility, chemotaxis, phagocytosis, and bactericidal dysfunction.[73] These changes can contribute to an increased risk of infection in hypophosphatemic patients. Animal studies also demonstrate platelet abnormalities in the setting of hypophosphatemia.[74] The implications of hypophosphatemia for human platelet function, however, have not been determined.

Finally, prolonged hypophosphatemia may result in osteopenia and osteomalacia because of enhanced osteoclastic resorption of bone and limited crystallization constituents (phosphate), respectively. Glucose intolerance from hypophosphatemia caused by tissue insensitivity to insulin has also been described.

CLINICAL PRESENTATION OF HYPOPHOSPHATEMIA

General

- The manifestations of hypophosphatemia depend on the chronicity and severity of the phosphate depletion. The major conditions associated with symptomatic hypophosphatemia are chronic alcoholism, intravenous hyperalimentation without adequate phosphate supplementation, and the chronic ingestion of antacids. Severe hypophosphatemia can also be seen during treatment of diabetic ketoacidosis and with prolonged hyperventilation.

Symptoms

- Except for the effects on mineral metabolism, the symptoms of hypophosphatemia are caused by two consequences (reduction of red cell 2,3-DPG and reduction of intracellular ATP levels), and can impact virtually all organ systems. The symptoms are predominantly neurological and can include irritability, apprehension, weakness, numbness, paresthesia, and confusion. Severe acute development of hypophosphatemia can result in seizures or coma.

Signs

- The initial response of bone to hypophosphatemia contributes to hypercalcemia and hypercalciuria. Prolonged hypophosphatemia can also result in rickets and osteomalacia.
- Neurologic: Severe hypophosphatemia can lead to a metabolic encephalopathy.
- Cardiopulmonary: Impaired myocardial contractility, respiratory failure secondary to ATP depletion, congestive heart failure, new onset or worsening of an existing condition.
- Musculoskeletal: Proximal myopathy, dysphagia, and ileus have been reported. Acute hypophosphatemia superimposed on preexisting severe phosphate depletion can lead to rhabdomyolysis.
- Hematologic: Alterations in the hematopoietic system can also occur, resulting in hemolysis, reduction in phagocytotic and granulocyte chemotactic ability, as well as defective clot retraction and thrombocytopenia.

Laboratory Tests

- Serum phosphate levels <2.4 mg/dL (<0.78 mmol/L) are indicative of hypophosphatemia; however, symptomatic hypophosphatemia typically is not evident until serum phosphate <1 mg/dL (<0.32 mmol/L).

TABLE 59-5 Phosphorus Replacement Therapy

Product (Salt)	Phosphate Content	Initial Dosing Based on Serum K
Oral therapy (potassium phosphate + sodium phosphate)		
Neutra-Phos (7 mEq/packet each of Na and K)	250 mg (8 mmol)/packet	1 packet 3 times daily[a]
Neutra-Phos-K (14.25 mEq/packet of K)	250 mg (8 mmol)/packet	Serum K >5.5 mEq/L (>5.5 mmol/L); not recommended
K-Phos Neutral (13 mEq/tablet Na and 1.1 mEq/tablet K)	250 mg (8 mmol)/tablet	Serum K >5.5 mEq/L (>5.5 mmol/L) 1 tablet 3 times daily
Uro-KP-Neutral (10.9 mEq/tablet Na and 1.27 mEq/tablet K)	250 mg (8 mmol)/tablet	Serum K >5.5 mEq/L (>5.5 mmol/L) 1 tablet 3 times daily
Fleets Phospho-soda (Sodium phosphate solution)	4 mmol/mL	Serum K >5.5 mEq/L (>5.5 mmol/L) 2 mL 3 times daily
Intravenous therapy		
Sodium PO_4 (4.0 mEq/mL Na)	3 mmol/mL	Serum K >3.5 mEq/L (>3.5 mmol/L) 15–30 mmol IVPB
Potassium PO_4 (4.4 mEq/mL K)	3 mmol/mL	Serum K <3.5 mEq/L (<3.5 mmol/L) 15–30 mmol IVPB

IVPB, intravenous piggyback; K, potassium; Na, sodium; PO_4, phosphate.
[a]Monitor serum K closely + intravenous piggy back.

TREATMENT

Hypophosphatemia

DESIRED OUTCOME

The goals of therapy are the reversal of signs and symptoms of hypophosphatemia, normalization of serum phosphate concentrations, and management of underlying conditions. Awareness of the clinical situations in which hypophosphatemia is anticipated (alcoholism, diabetic ketoacidosis, and parenteral nutrition) is of vital importance in preventing iatrogenic hypophosphatemia. The routine addition of phosphate in concentrations of 12 to 15 mmol/L to intravenous hyperalimentation solutions is of utmost importance for the prevention of severe hypophosphatemia in hospitalized patients.

PHARMACOLOGIC THERAPY

8 Severe (<1 mg/dL [<0.32 mmol/L]) or symptomatic hypophosphatemia should be treated with parenteral phosphate replacement. Oral phosphate supplementation is usually reserved for patients who are asymptomatic or who exhibit mild to moderate hypophosphatemia. Estimation of total body phosphate deficit is difficult because phosphate is an intracellular electrolyte. Dosage and infusion recommendations, as well as response to parenteral phosphate replacement, are highly variable.[81] The infusion of 15 mmol of phosphate in 250 mL 5% dextrose or 0.9% sodium chloride over 3 hours is a safe and effective treatment for severe hypophosphatemia.[81] Mean increases in serum phosphate of 0.5 to 0.8 mg/dL (0.16–0.26 mmol/L) have been reported. Doses of 15 to 30 mmol of phosphate can be given over 1 to 3 hours in patients without hypercalcemia (serum calcium >10.5 mg/dL [>2.63 mmol/L]).[84] Other authors recommend a wider dosage range of 0.08 to 0.64 mmol/kg body weight (5–45 mmol in a 70-kg [154 lb] patient) given over 4 to 12 hours.[85] Intravenous phosphate therapy produces the desired increase in serum phosphate at 24 hours in 20% to 80% of patients. Response is dependent on the degree of phosphate depletion and replacement dose administered.[65] Furthermore, the initial success is often followed in 48 to 72 hours by recurrent hypophosphatemia, necessitating close monitoring of serum phosphate and repeated administration of phosphate products as warranted.

Parenteral phosphate supplementation is associated with risks of hyperphosphatemia, metastatic soft tissue deposition of calcium-phosphate product, hypomagnesemia, hypocalcemia, and hyperkalemia or hypernatremia (caused by intravenous phosphate salt) (Table 59–5). Inappropriate administration of large doses of parenteral phosphate over relatively short time periods has resulted in symptomatic hypocalcemia and soft-tissue calcification.[65] The rate of infusion and choice of initial dosage should therefore be based on severity of hypophosphatemia, presence of symptoms, and coexistent medical conditions. Patients should be closely monitored with frequent (every 6 hours) serum phosphate determinations for 48 to 72 hours after starting intravenous therapy. It can be necessary to continue administration of intravenous phosphate for several days in some patients, although other patients may be able to tolerate an oral maintenance regimen. Monitoring should also include assessment of serum potassium, calcium, and magnesium concentrations. Hypomagnesemia secondary to intracellular shifts occurs frequently (27%–80%) in severely hypophosphatemic patients.[81] Therapy with parenteral phosphate should be undertaken with great caution and at reduced dosage for patients with hypercalcemia or renal dysfunction.[73,83]

Mild to moderate or asymptomatic hypophosphatemia can be treated by the administration of oral phosphate salts in doses of 1.5 to 2 g (50–60 mmol) daily in divided doses (see Table 59–5). Phosphate concentrations should be monitored daily, with the goal of correcting the reduced phosphate concentration in approximately 7 to 10 days. The primary dose-limiting adverse effect associated with oral phosphate replacement is the development of osmotic diarrhea. Patients with mild to moderate hypophosphatemia and moderate to severe renal insufficiency should receive reduced daily oral doses (i.e., 1 g or approximately 30 mmol of phosphate) with careful monitoring of serum phosphate concentration because they are predisposed to phosphate retention. In addition to phosphate supplementation for hypophosphatemia, dipyridamole can decrease renal phosphate leaking and increase serum phosphate. Doses of 75 mg 4 times daily have resulted in increases in serum 1,25-dihydroxy vitamin D_3 and decreases in serum calcium and urolithiasis events.[86]

CONCLUSIONS

Clinicians play an integral part in the management of fluid and electrolyte abnormalities. Initial treatment strategy should be based on acuity of onset and severity of symptoms. Because the etiologies of calcium and phosphate disorders are diverse, it is important to integrate the known or anticipated pathophysiologic disease course into the treatment strategy. The patient's medication history should be comprehensively assessed to determine whether the electrolyte abnormality may be drug induced. After resolution or treatment of the calcium or phosphate disorder, the medication regimen should be evaluated periodically. This proactive interventional approach will facilitate the management of mild disorders in the community and can reduce the need for hospitalization.

ABBREVIATIONS

ATP: adenosine triphosphate

CHF: congestive heart failure

CKD: chronic kidney disease

CNS: central nervous system

FGF23: fibroblast growth factor 23

2,3-DPG: 2,3-diphosphoglycerate

NSAID: nonsteroidal anti-inflammatory drug

PTH: parathyroid hormone

PTHrP: PTH-related protein

S_{ca}: serum calcium

CHAPTER 60

Disorders of Potassium and Magnesium Homeostasis

DONALD F. BROPHY AND JANE FRUMIN

KEY CONCEPTS

1. Potassium is the primary intracellular ion in the human body.
2. The normal serum potassium concentration range is 3.5 to 5 mEq/L (3.5–5 mmol/L).
3. Potassium regulates many biochemical processes in the body and is a key ion for electrical action potentials across cellular membranes.
4. In patients with concomitant hypokalemia and hypomagnesemia, it is imperative to correct the hypomagnesemia before the hypokalemia.
5. Potassium chloride is the preferred potassium supplement for the most common causes of hypokalemia.
6. Hyperkalemia is a common occurrence in patients with acute or chronic kidney disease.
7. Magnesium is an important cofactor for many cellular functions.
8. The normal serum magnesium concentration range is 1.4 to 1.8 mEq/L (0.70–0.90 mmol/L).
9. Hypomagnesemia is commonly caused by excessive gastrointestinal or renal magnesium wasting.
10. Hypermagnesemia is commonly observed in patients with acute or chronic kidney disease.

Potassium and magnesium are electrolytes that are responsible for numerous metabolic activities. Disorders of these electrolytes are frequently seen in both the acute care and community ambulatory care settings. Therefore, clinicians need a firm understanding of the etiology, pathophysiology, symptoms, pharmacotherapy, and monitoring of these disorders. This chapter describes the homeostatic mechanisms that are responsible for the maintenance of normal potassium and magnesium serum concentrations. The clinical disorders responsible for the development of hyperkalemia, hypermagnesemia, hypokalemia, and hypomagnesemia are also reviewed.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

POTASSIUM

1 Potassium is the most abundant cation in the body, with estimated total-body stores of 3,000 to 4,000 mEq (3,000–4,000 mmol).[1] Ninety-eight percent of this amount is contained within the intracellular compartment, and the remaining 2% is distributed within the extracellular compartment. The sodium potassium adenosine triphosphatase (Na^+-K^+-ATPase) pump located in the cell membrane is responsible for the compartmentalization of potassium. This pump is an active transport system that maintains increased intracellular stores of potassium by transporting sodium out of the cell and potassium into the cell at a ratio of 3:2. Consequently, the pump maintains a higher concentration of potassium inside the cell.

2 The normal serum concentration range for potassium is 3.5 to 5.0 mEq/L (3.5–5.0 mmol/L), whereas the intracellular potassium concentration is usually approximately 150 mEq/L (150 mmol/L).[2] Approximately 75% of the intracellular potassium is located in skeletal muscle; the remaining 25% is located in the liver and red blood cells. Extracellular potassium is distributed throughout the serum and interstitial space. Potassium is dynamic in that it is constantly moving between the intracellular and extracellular compartments according to the body's needs. Thus the serum potassium concentration alone does not accurately reflect the total-body potassium content.

3 Potassium has many physiologic functions within cells, including protein and glycogen synthesis and cellular metabolism and growth. It is also a determinant of the electrical action potential across the cell membrane.[1] The ratio of the intracellular to extracellular potassium concentration is the major determinant of the resting membrane potential across the cell membrane. Thus the resting membrane potential is greatly affected by variations in extracellular potassium concentration. Serum potassium concentrations outside the normal range can have disastrous effects on neuromuscular activity, in particular cardiac conduction. Hypo- and hyperkalemia are both associated with potentially fatal cardiac arrhythmias, along with other neuromuscular disturbances. Finally, potassium is integral to maintaining healthy blood pressure balance; indeed, both the National High Blood Pressure Education Program and the Institute of Medicine recommend potassium supplementation as strategies for preventing and treating hypertension.[3–5]

CONTROL OF POTASSIUM HOMEOSTASIS

Potassium homeostasis, the maintenance of serum potassium within the normal range, is affected by dietary intake, gastrointestinal and urinary excretion, hormones, acid–base balance, body fluid tonicity and a highly integrated feedback mechanism.[6,7]

The recommended daily allowance for dietary potassium intake is approximately 50 mEq/day. Potassium is found in abundance in

fruits, vegetables, and meats. The typical American ingests approximately 50 to 150 mEq (50–150 mmol) of potassium daily. Nearly all of this is absorbed, with only 10 to 20 mEq/day (10–20 mmol/day) eliminated in feces. The amount eliminated in the feces increases, however, in patients with diarrhea and in those with chronic kidney disease (CKD).[7]

The kidney is the primary route of potassium elimination. Potassium is freely filtered but almost all of it is reabsorbed passively in the proximal tubule and the thick ascending limb of the loop of Henle.[8] Therefore urinary potassium excretion is primarily determined by potassium secretion from the luminal cells of the distal tubule and collecting duct. Although the amount of potassium filtered by the glomerulus approaches 700 mEq (700 mmol) per day, only approximately 10% to 20% is actually excreted in the urine.[8] However, this amount can vary based on dietary intake, serum potassium concentration, and aldosterone activity. For example, more potassium is renally excreted in conditions that result in high aldosterone activity (e.g., dehydration) when the body is attempting to conserve sodium or when there is an increase in dietary potassium intake.

Hormones such as insulin, catecholamines, and aldosterone dramatically affect potassium homeostasis. Insulin is the most important hormonal mediator of potassium balance because it stimulates the cellular Na^+-K^+-ATPase pump to increase transport of potassium into liver, muscle, and adipose tissue.[6] There is a complex negative feedback loop in which insulin secretion tightly regulates serum potassium concentrations: an increase of only a few tenths of a milliequivalent of potassium stimulates pancreatic insulin secretion in an attempt to prevent hyperkalemia from developing.[1] If hyperkalemia does occur, glucagon is released from the liver to protect against insulin-induced hypoglycemia. Conversely, hypokalemia inhibits insulin secretion, a finding that explains why some patients receiving diuretics develop hyperglycemia.

An elevation in circulating catecholamines such as epinephrine usually results in the intracellular movement of potassium by two mechanisms.[8] They stimulate the β-receptor, which directly activates the Na^+-K^+-ATPase pump. Second, they stimulate glycogenolysis, which raises blood glucose concentrations, thereby increasing insulin secretion. This dual mechanism is often used therapeutically in patients with hyperkalemia to normalize serum potassium concentrations.

Aldosterone, a mineralocorticoid that is secreted from the adrenal glands in response to high serum potassium concentrations, promotes urinary potassium excretion. Aldosterone works in the distal tubule and collecting duct to promote the reabsorption of sodium and water in exchange for potassium. Aldosterone may also have extrarenal activity by stimulating cellular Na^+-K^+-ATPase pump activity.[8]

Changes in acid–base status significantly affect the serum potassium concentration. For example, the infusion of metabolic inorganic acids, such as hydrochloric acid, results in an increase in serum potassium. The body compensates for excessive hydrogen ions by moving them from the serum into the cell in exchange for intracellular potassium, to maintain electroneutrality. The process by which this occurs is complex, and a cellular H^+-K^+-ATPase pump has been identified. The efflux of potassium into the serum can result in hyperkalemia. A commonly quoted approximation of the pH effect is that for every 0.1 unit decrease in pH, there is a corresponding increase in serum potassium of 0.6 to 0.8 mEq/L (0.6–0.8 mmol/L) (with a wide range of 0.2–1.7).[5] This is often referred to as *false hyperkalemia* because there is not a true excess of total-body potassium. Metabolic acidosis associated with lactic acidosis and ketoacidosis, does not result in hyperkalemia, because both cations and anions enter the cell, thus maintaining electroneutrality.[1] Respiratory acidosis also does not significantly affect the serum potassium concentration.

Conversely, metabolic alkalosis has been associated with hypokalemia. As a result of a net loss of hydrogen ion from the serum, intracellular hydrogen ions enter the serum to increase the acidity of the blood. To maintain electroneutrality extracellular potassium ions are shifted intracellularly. This creates a relative deficiency of potassium in the serum. Serum potassium decreases approximately 0.6 mEq/L (0.6 mmol/L) for each 0.1 unit increase in blood pH. This is frequently termed *false hypokalemia* because there is not a true deficiency in total-body potassium.

Finally, hyperosmolality can result in enhanced movement of potassium from the cell into the extracellular fluid. This occurs most likely because of the associated cell shrinkage and water loss, which increases the intracellular-to-extracellular potassium gradient.[3] This is seen most commonly in conditions such as diabetic ketoacidosis. Conversely, hypo osmolality does not seem to affect potassium distribution.

HYPOKALEMIA

Epidemiology

Hypokalemia (defined as a serum potassium concentration <3.5 mEq/L [<3.5 mmol/L]) is a commonly encountered electrolyte abnormality in clinical practice. Hypokalemia can be categorized as mild (serum potassium 3.1–3.5 mEq/L [3.1–3.5 mmol/L]), moderate (serum potassium 2.5–3.0 mEq/L [2.5–3.0 mmol/L]), or severe (<2.5 mEq/L [<2.5 mmol/L]).[9] When hypokalemia is detected, a diagnostic workup that evaluates the patient's comorbid disease states and concomitant medications should be initiated. Hypokalemia is virtually nonexistent in healthy adults. This is due in part to the relatively high potassium content in the typical Western diet as well as the body's effective potassium-sparing mechanisms, which tightly regulate the serum potassium concentration. However it has been estimated that as many as 50% of patients who receive thiazide or loop diuretics have serum potassium concentrations less than 3.5 mEq/L (3.5 mmol/L).[10]

Etiology and Pathophysiology

Hypokalemia results when there is a total-body potassium deficit, or when serum potassium is shifted into the intracellular compartment. Total-body deficits occur in the setting of poor dietary intake of potassium, or when there are excessive renal and gastrointestinal losses of potassium.

Maintaining a consistent dietary intake of potassium is important because the body has no effective method for storing potassium. At steady state, potassium excretion matches potassium intake; approximately 90% of ingested potassium is renally excreted, whereas 10% is excreted in feces.[8] This underscores the importance of eating a well-balanced diet. Elderly patients with chronic diseases and those undergoing surgery are at increased risk for developing hypokalemia because of insufficient intake or losses resulting from surgery.

Many drugs can cause hypokalemia by a variety of mechanisms including intracellular potassium shifting and increased renal or stool losses (Table 60–1). The most common cause of drug-induced hypokalemia is loop and thiazide diuretic administration as these agents inhibit renal sodium reabsorption, which results in increased sodium delivery to the distal tubule. Consequently, hypokalemia develops because the distal tubule selectively reabsorbs sodium, and excretes potassium down its concentration gradient. Second, because diuretics result in volume contraction, aldosterone is secreted which further promotes the renal excretion of potassium. If concomitant potassium supplements are not provided to patients receiving loop and thiazide diuretics, mild to moderate hypokalemia is inevitable.

The second most common etiology of hypokalemia is excessive loss of potassium-rich GI fluid as a result of diarrhea and/or

TABLE 60-1 Mechanism of Drug-Induced Hypokalemia

	Cisplatin	

vomiting. The typical potassium loss in feces is approximately 10 mEq (10 mmol) per day.[7] In diarrheal states, this amount increases proportionally with the volume of stool output. Vomiting also accounts for substantial potassium losses, which have been estimated to be as high as 30 to 50 mEq (30–50 mmol) per liter of vomitus.[10] Metabolic alkalosis can also occur in cases of severe diarrhea and vomiting as a result of loss of these bicarbonate-rich fluids. This causes an intracellular shifting of potassium, which lowers the serum concentration of potassium even further. Prolonged diarrhea and vomiting can significantly affect children and elderly patients because their kidneys are unable to effectively maintain adequate fluid status.

4 Hypomagnesemia, which is present in more than 50% of cases of clinically significant hypokalemia, contributes to the development of hypokalemia because it reduces the intracellular potassium concentration and promotes renal potassium wasting.[11] While the precise mechanism of the accelerated renal loss is unknown, many believe that the intracellular potassium concentration may decrease because hypomagnesemia impairs the function of the Na^+-K^+-ATPase pump thereby promoting K+ wasting. Alternatively, the combination of increased sodium delivery to the distal tubule, elevated aldosterone concentrations, and hypomagnesemia may cause the renal outer meduallary potassium channels to excrete potassium.[11] What is clear is that hypokalemia and hypomagnesemia often coexist as a result of drugs (diuretic administration) or disease states (diarrhea). When concomitant hypokalemia and hypomagnesemia occur, the magnesium deficiency should be corrected first, otherwise full repletion of the potassium deficit is difficult.

CLINICAL PRESENTATION OF HYPOKALEMIA

General

- The signs and symptoms of hypokalemia are usually nonspecific and highly variable between patients.

Symptoms

- Symptoms are highly dependent on the degree of hypokalemia and its rapidity of onset.
- Mild hypokalemia is often asymptomatic.
- Moderate hypokalemia is associated with cramping, weakness, malaise, and myalgias.

Signs

- Cardiovascular: In severe hypokalemia, electrocardiogram (ECG) changes often include ST-segment depression or flattening, T-wave inversion, and U-wave elevation. Clinical arrhythmias include heart block, atrial flutter, paroxysmal atrial tachycardia, ventricular fibrillation, and digitalis-induced arrhythmias.
- Musculoskeletal: Cramping and impaired muscle contraction.

Laboratory Tests

- Serum potassium concentration <3.5 mEq/L (<3.5 mmol/L) is diagnostic. Hypomagnesemia (serum magnesium concentration <1.7 mg/dL [<0.70 mmol/L]) can also be present.

TREATMENT

Hypokalemia

DESIRED OUTCOME

The goals of hypokalemia management are to prevent its development, treat serious life-threatening complications, normalize the serum potassium concentration, identify and correct the underlying cause of hypokalemia, and finally prevent overcorrection of the serum potassium concentration.

GENERAL APPROACH TO THERAPY

The general approach to therapy depends on the degree and rapidity with which hypokalemia developed and the presence of symptoms. Serum potassium concentrations between 3.5 and 4 mEq/L (3.5 and 4 mmol/L) are a sign of early potassium depletion. No pharmacologic therapy is recommended at this point; however, these patients should be encouraged to increase their dietary intake of potassium-rich foods. When the serum potassium concentration is between 3.0 and 3.5 mEq/L (3.0 and 3.5 mmol/L), it is debatable whether pharmacologic therapy should be initiated. Oral potassium supplementation should be initiated in patients with underlying cardiac conditions that predispose them to cardiac arrhythmias.[12] This includes patients receiving concomitant digoxin therapy. Patients with serum potassium concentrations below 3.0 mEq/L (3.0 mmol/L) should always be treated to achieve values between 4.0 and 4.5 mEq/L (4.0 and 4.5 mmol/L). In asymptomatic patients, oral therapy is the preferred route of administration. Intravenous (IV) potassium can be necessary in symptomatic patients with severe depletion, or in patients who are intolerant to oral supplementation. In patients with concomitant moderate to severe hypomagnesemia, the magnesium deficit should be corrected before potassium supplementation, to prevent refractory hypokalemia.[8,13]

NONPHARMACOLOGIC THERAPY

Various nonpharmacologic therapies have been used to prevent and treat hypokalemia. The best and most abundant source of potassium supplementation comes from dietary sources, in particular, fresh fruits and vegetables, fruit juices, and meats.[13] Table 60–2 lists foods that are excellent sources of potassium. Salt substitutes that contain potassium chloride are another effective, inexpensive source of potassium. Increased dietary intake of foods with high potassium content however is not recommended long term for many patients because it can add unwanted calories to the patient's diet. Moreover, dietary potassium is almost entirely coupled with

TABLE 60-2 Foods That Are High in Potassium

High content (>250 mg/100 g)	**Highest content (>1,000 mg/100 g)**
Vegetables	Dried figs
Spinach	Molasses

phosphate, rather than chloride, so it is not as effective in correcting potassium loss associated with hypochloremic conditions such as vomiting, nasogastric suctioning, and diuretic therapy.[13]

PHARMACOLOGIC THERAPY

Formal guidelines for potassium supplementation were last published by the National Council on Potassium in Clinical Practice in 2000 (Table 60–3).[13] These guidelines provide a comprehensive framework for potassium administration as a prophylactic and therapeutic replacement in many distinct patient populations. When deciding how to design the optimal regimen one must consider: (1) the patient's normal baseline potassium concentration; (2) underlying medical conditions that can affect potassium balance; (3) concomitant medications that can affect potassium balance; (4) the patient's dietary and salt intake; and (5) the patient's ability to comply with the therapeutic regimen.[13]

A general rule for potassium replacement is that for every 1 mEq/L (1 mmol/L) decrease of potassium below 3.5 mEq/L (3.5 mmol/L), there is a corresponding total-body potassium deficit of 100 to 400 mEq (100–400 mmol). Because of the wide variance in projected deficits, each patient's therapy must be individualized and adjustments made on the basis of the patient's signs, symptoms, and frequent measurements of serum potassium. In patients receiving chronic loop or thiazide diuretic therapy, 40 to 100 mEq (40–100 mmol) of oral potassium supplementation can correct mild to moderate potassium deficits. Doses up to 120 mEq (120 mmol) can be required in more severe deficiencies. When providing oral potassium supplementation, the total daily dose should be divided into three to four doses to minimize the development of GI side effects. Patients receiving diuretics can become chronically hypokalemic and can benefit from combination potassium-sparing diuretic therapy.

CLINICAL CONTROVERSY

The replacement of potassium intravenously can be accomplished by IV piggyback or Buretrol administration. A pharmacist usually prepares the potassium IV piggyback, double checks the concentration and fluid, and then dispenses the final product to the medical unit. However, with Buretrol administration, essentially any clinician (e.g., nurse or physician) can prepare the solution on the medical unit and infuse the potassium solution into the patient. The Joint Commission and the United States Pharmacopeia 797 Standards now advocate that all parenteral products be compounded in a sterile, laminar flow environment, and be double-checked by a pharmacist to assure patient safety. Many hospitals to date have not adapted these recommendations, which were developed to improve patient safety.

5 Whenever possible, potassium supplementation should be administered by mouth. Three salts are available for oral potassium supplementation: chloride, phosphate, and bicarbonate. Potassium phosphate should be used when patients are both hypokalemic and hypophosphatemic; potassium bicarbonate is most commonly used when potassium depletion occurs in the setting of metabolic acidosis. Potassium chloride, however, is the primary salt form used because it is the most effective treatment for the most common causes of potassium depletion (i.e., diuretic-induced and diarrhea-induced) as these conditions are associated with potassium and chloride losses.

TABLE 60-3 General Consensus Guidelines for Potassium Replacement

Guideline	**Comment**
Potassium replacement therapy should accompany dietary consumption of potassium-rich foods.	Potassium-rich foods often cannot completely replace potassium associated with chloride losses (vomiting, diuretics, or nasogastric suction) because it is almost entirely coupled to phosphate. Furthermore, increasing dietary intake of these foods can lead to unwanted weight gain.
Potassium replacement is recommended for sodium sensitive and hypertensive patients.	A high-sodium diet often results in excessive urinary potassium excretion.
Potassium replacement is recommended in patients who are subject to vomiting, diarrhea, or diuretic/laxative abuse.	These conditions promote excessive renal and GI potassium loss.
Potassium supplementation is best administered orally in divided doses over several days to achieve full repletion.	
Laboratory measurement of serum potassium is convenient but not always accurate.	Clinicians should be aware of the factors that result in transcellular potassium shifts. Monitoring 24-hour urinary potassium excretion can be necessary in high-risk patients.
Patient adherence to potassium replacement can be increased with compliance-enhancing regimens.	Microencapsulated products have no bitter smell or aftertaste and have much better GI tolerance. Regimens should be made as simple as possible to follow.
A potassium dosage of 20 mEq/day (20 mmol/day) is usually sufficient to prevent hypokalemia from occurring. Doses of 40–100 mEq (40–100 mmol) are usually sufficient to treat hypokalemia.	

TABLE 60-4 Differentiation of Available Potassium Supplements

Supplement	Comment
Controlled-release microencapsulated tablet	Disintegrates better in GI tract; fewer GI erosions as compared to wax-matrix tablets
Encapsulated controlled-release microencapsulated particles	Fewer erosions as compared to wax-matrix tablets
Potassium chloride elixir	Inexpensive, poor taste, poor compliance, immediate effect
Potassium chloride effervescent tablets for solution	More expensive than elixir, convenient
Wax-matrix extended-release tablets	Easier to swallow; more GI erosions as compared to other therapies

Potassium chloride can be administered in either tablet or liquid formulations (Table 60–4). The liquid forms are generally less expensive; however, patient compliance can be low because of their strong, unpleasant taste. Two sustained-release solid dosage forms are currently available in the United States: a wax-matrix formulation, and a microencapsulated formulation. The microencapsulated tablet is generally preferred because it disintegrates better in the stomach and is associated with less GI irritation.[13]Intravenous potassium use should be limited to: (1) severe cases of hypokalemia (serum concentration <2.5 mEq/L [<2.5 mmol/L]); (2) patients exhibiting signs and symptoms of hypokalemia such as ECG changes or muscle spasms; or (3) patients unable to tolerate oral therapy. Intravenous supplementation is more dangerous than oral therapy because it is more likely to result in hyperkalemia, phlebitis, and pain at the site of infusion.

The vehicle in which IV potassium is administered is important. Whenever possible, potassium should be prepared in saline-containing solutions (e.g., 0.9% or 0.45% sodium chloride [NaCl]). Dextrose-containing solutions stimulate insulin secretion, which can cause intracellular shifting of potassium, worsening the patient's hypokalemia, and should be avoided whenever possible.[14] Generally, 10 to 20 mEq (10–20 mmol) of potassium is diluted in 100 mL 0.9% NaCl for IV administration. These concentrations are safe when administered through a peripheral vein over one hour. When infusion rates exceed 10 mEq/h (10 mmol/h), ECG monitoring should be performed to detect cardiac changes. The serum potassium concentration should be evaluated following the infusion of each 30 to 40 mEq (30–40 mmol) to direct further potassium replacement requirements. Multiple doses of potassium can be repeated as needed until the serum potassium concentration normalizes. To allow adequate time for the potassium to equilibrate between the intra- and extracellular spaces, the clinician should wait at least 30 minutes from the end of each infusion before obtaining a serum concentration. Care should be taken to avoid sampling from the same line in which the potassium was infused, as this can result in a spuriously high potassium concentration.

In cases of severe potassium depletion, patients can require as much as 300 to 400 mEq/day (300–400 mmol/day). In this instance, it is common practice to dilute 40 to 60 mEq (40–60 mmol) in 1,000 mL 0.45% NaCl and infuse at a rate not exceeding 40 mEq/h (40 mmol/h). This should be performed in an intensive care unit under continuous ECG monitoring. Because of the high potassium concentration, and the risk for burning pain and peripheral venous sclerosis, the infusion should be through a central venous catheter into a large vein (e.g., superior vena cava) but care must be taken not to place the tip of the catheter into the right atrium.[15] Directly delivering high potassium concentrations into the heart can result in cardiac arrhythmias. Given the volume required to infuse this dose of potassium, this infusion strategy might be impractical in certain clinical situations (e.g., patients requiring fluid restriction). A reasonable alternative is to split the potassium dose between the oral and IV routes. For example, if a symptomatic patient requires 120 mEq (120 mmol) of potassium, the clinician can give 60 mEq (60 mmol) as the immediate-release potassium liquid, and the other 60 mEq (60 mmol) can be given through the IV route (20 mEq/100 mL/h [20 mmol/100mL/h] in three doses). When giving large potassium doses, serum monitoring should be performed following the administration of half the dose to guide the clinician as to the need for additional potassium. This can also help avoid the development of hyperkalemia.

In the rare circumstances when cardiac arrest from hypokalemia is imminent, IV bolus dosing of potassium 10 mEq (10 mmol) over 5 minutes can be initiated and repeated once, if necessary.[15]

ALTERNATIVE THERAPIES

Potassium-sparing diuretics are an alternative to chronic exogenous potassium supplementation, especially when patients are concomitantly receiving drugs that are known to deplete potassium (e.g., diuretics or amphotericin B). Spironolactone inhibits the effect of aldosterone in the distal convoluted tubule, thereby decreasing potassium elimination in the urine. Spironolactone is especially effective as a potassium-sparing agent in patients with primary or secondary hyperaldosteronism. Amiloride and triamterene act by an aldosterone-independent mechanism; however, the precise mechanism of their potassium sparing is unknown.

Spironolactone is available as 25-mg, 50-mg, and 100-mg tablets. The usual starting dose is 25 to 50 mg daily, and can be titrated to a maximum dose of 400 mg/day. The potassium-retaining effects generally take approximately 48 hours to occur. Important side effects include hyperkalemia, gynecomastia, breast tenderness, and impotence in men.

Triamterene is available as 50-mg and 100-mg capsules. The usual starting dose is 50 mg twice daily, which can be titrated to 100 mg twice daily. Triamterene 50 mg is available as a combination product with hydrochlorothiazide 25 mg and is commonly used for the treatment of hypertension. Common side effects include hyperkalemia, sodium depletion, and metabolic acidosis.

Amiloride is available as a 5-mg tablet. The usual starting dose is 5 mg daily; however, 10 mg can be given in those with severe hypokalemia. This is also available as a combination product with hydrochlorothiazide 50 mg. The most common side effects are hyperkalemia and metabolic acidosis.

Generally, concomitant use of potassium supplementation with potassium-sparing diuretics is not necessary. There is a significant risk of hyperkalemia during combination therapy, especially in patients with underlying renal insufficiency or diabetes mellitus.

While there have been no pharmacoeconomic evaluations of the different pharmacotherapeutic alternatives to manage hypokalemia, the most convenient source of chronic potassium supplementation is appropriate dietary intake of potassium-rich foods.

EVALUATION OF THERAPEUTIC OUTCOMES

Serum potassium concentrations should be monitored regularly while the patient is receiving potassium supplementation. For patients receiving prophylactic potassium supplementation during diuretic therapy, the serum potassium and magnesium concentrations, as well as renal function should be monitored every 1 to 2 months in stable patients. In hospitalized patients receiving oral therapy for mild hypokalemia, the potassium concentration should be monitored every 2 to 3 days. Generally, the

potassium concentration begins to increase within 72 hours. If it does not increase by at least 1 mEq/L (1 mmol/L) within 96 hours, the clinician should suspect concomitant magnesium depletion. Patients receiving IV potassium supplementation require close ECG monitoring if the infusion rate is >20 mEq/h (>20 mmol/h). Doses greater than this should be administered only in the presence of continuous ECG monitoring. Additionally, the patient should have potassium concentrations obtained halfway through, and 30 minutes following completion of the total potassium dose to guide further potassium dosing. Finally, the patient should be assessed for adverse effects such as pain at the infusion site or phlebitis.

HYPERKALEMIA

Hyperkalemia, defined as a serum potassium concentration greater than 5.0 mEq/L (>5.0 mmol/L), can be further classified according to its severity: mild hyperkalemia (5.1–5.9 mEq/L [5.1–5.9 mmol/L]), moderate hyperkalemia (6.0–7.0 mEq/L [6.0–7.0 mmol/L]), and severe hyperkalemia (>7 mEq/L [>7 mmol/L]).[18]

Epidemiology

6 Hyperkalemia is much less common than hypokalemia. In fact, if all patients with acute and chronic kidney disease were excluded, the true prevalence of hyperkalemia would be insignificant. The incidence of hyperkalemia in hospitalized patients is highly variable, and reports have ranged from 1.4% to 10%.[13] Most cases of hyperkalemia are the result of overcorrection of hypokalemia with IV potassium supplements. Severe hyperkalemia occurs more commonly in elderly patients with renal insufficiency who receive chronic oral potassium supplementation.[17,18]

Etiology and Pathophysiology

Hyperkalemia develops when potassium intake exceeds excretion (true hyperkalemia) (i.e., elevated total-body stores), or when the transcellular distribution of potassium is disturbed (i.e., normal total-body stores). The four primary causes of hyperkalemia—(1) increased potassium intake, (2) decreased potassium excretion, (3) tubular unresponsiveness to aldosterone, and (4) redistribution of potassium into the extracellular space—are discussed below.

Hyperkalemia Associated with Increased Potassium Intake

Hyperkalemia in this setting is almost always associated with renal insufficiency. Patients with stage 4 or 5 CKD and dialysis patients who are noncompliant with dietary potassium restrictions often present with life-threatening hyperkalemia. Many of these patients do not realize that fresh fruits and vegetables contain large amounts of potassium. Anecdotally, in many dialysis centers the incidence of hyperkalemia peaks during the summer months, when fresh garden produce is available. Another common dietary source associated with the development of hyperkalemia is potassium chloride salt substitutes. Many dialysis patients are instructed to use salt substitutes to avoid excessive sodium intake in an attempt to control volume overload. These patients unwittingly become hyperkalemic because these products contain approximately 10 to 15 mEq (10–15 mmol) potassium per gram, or 200 mEq (200 mmol) per tablespoon. Finally, many over-the-counter herbal and alternative medicine products may contain significant concentrations of potassium.[19–20]

It is essential for patients with CKD to receive education regarding dietary sources of potassium as well as information on the potassium content of herbal products because the ingestion of these can lead to hyperkalemia.

Hyperkalemia Associated with Decreased Renal Potassium Excretion

The kidneys excrete 80% of the daily potassium intake. Therefore, when the kidney is unable to excrete potassium appropriately, as in acute kidney injury (AKI) and stage 4 to 5 CKD, potassium is retained and often results in hyperkalemia. Finally, many drugs can inhibit the kidney's ability to excrete potassium by inhibiting aldosterone and thus contribute to an increase in serum potassium concentrations.

Severe hyperkalemia is more common in AKI than in CKD because patients are often hypercatabolic and can have underlying disorders, such as rhabdomyolysis or tumor lysis syndrome, which result in release of potassium from injured or lysed cells.[21] Severe hyperkalemia is rare in stable CKD patients, perhaps because of enhanced GI and renal potassium excretion.[22] Data suggest that hyperkalemia directly stimulates renal K^+ excretion through an effect that is independent of, and additive to, that of aldosterone.[22] Although the overall incidence of hyperkalemia is higher in patients with CKD when compared to patients without CKD, due to these adaptive mechanisms and their decreased susceptibility to cardiac effects of chronic hyperkalemia, it has been associated with a lower mortality rate.[18] Renal excretion of potassium is also inhibited by various endocrinologic disorders, including adrenal insufficiency, Addison's disease, and selective hypoaldosteronism. All of these disorders involve a decreased production of aldosterone, which results in the retention of potassium.

Several drugs have profound effects on the kidney's ability to regulate potassium.[23] Four drug classes in particular have specific effects on the kidney: angiotensin-converting enzyme inhibitors (ACEIs), angiotensin-II receptor blockers (ARBs), potassium-sparing diuretics, and prostaglandin inhibitors such as nonsteroidal anti-inflammatory drugs (NSAIDs). Although hyperkalemia with these drugs is typically dose dependent, the rates of hyperkalemia have been reported to range from 5% to 10% in most clinical trials. Other commonly used drugs that can cause hyperkalemia are digoxin, cyclosporine, tacrolimus, trimethoprim-sulfamethoxazole, heparin, and pentamidine.[23]

Tubular Unresponsiveness to Aldosterone

Certain medical conditions, such as sickle cell anemia, systemic lupus erythematosus, and amyloidosis, can produce a defect in tubular potassium secretion, possibly as the result of an alteration in the aldosterone-binding site. The exact mechanism of the tubular unresponsiveness is unknown.

Redistribution of Potassium into the Extracellular Space

The efflux of potassium from within the cell into the extracellular fluid, which is associated with no change in total-body potassium stores, is to be expected in the presence of metabolic acidosis, diabetes mellitus, chronic renal failure, or lactic acidosis. β-Blockers can also result in a transcellular potassium shift.[23]

The serum potassium concentration can also be falsely elevated in some conditions, and not reflect the actual in vivo potassium concentration. This is termed *pseudohyperkalemia*. Pseudohyperkalemia occurs most commonly in the setting of extravascular hemolysis of red blood cells. When a blood specimen is not processed promptly and cellular destruction occurs, intracellular potassium is released into the serum. Pseudohyperkalemia can also occur in conditions of thrombocytosis or leukocytosis. If severe hyperkalemia is found in a patient who is asymptomatic with an otherwise normal laboratory report, the hyperkalemia is most likely pseudohyperkalemia, and a repeat blood sample should be evaluated. Truly elevated potassium concentrations are normally associated with other

laboratory abnormalities, such as low carbon dioxide (acidosis) or elevated blood urea nitrogen and creatinine concentrations (indicating renal insufficiency).

CLINICAL PRESENTATION OF HYPERKALEMIA

General

- Related to the effects of excessive potassium on neuromuscular, cardiac, and smooth muscle cell function.

Symptoms

- Frequently asymptomatic.
- The patient might complain of heart palpitations or skipped heartbeats.

Signs

- ECG changes (see Fig. 60–1 for description).

Laboratory Tests

- Serum potassium concentration >5.5 mEq/L (>5.5 mmol/L).

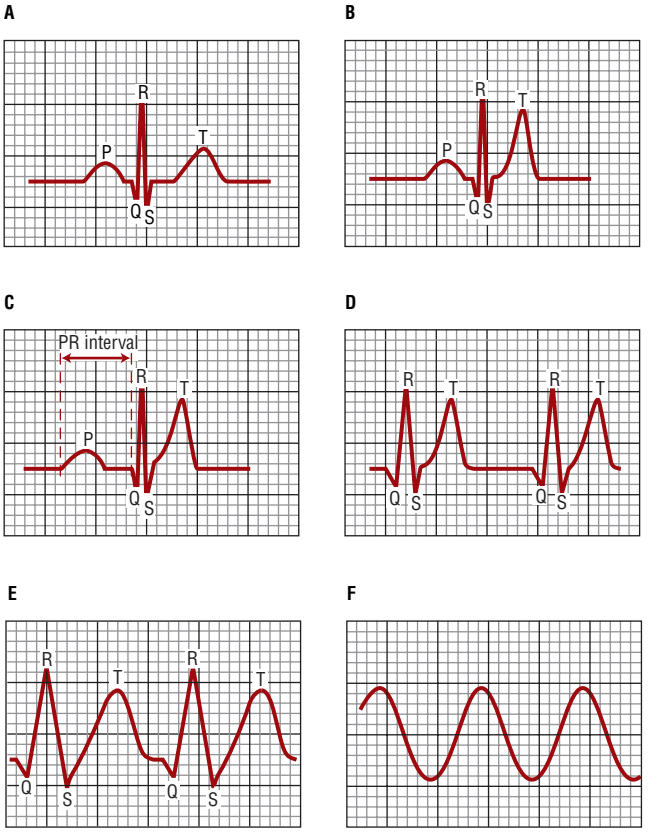

FIGURE 60-1. The earliest electrocardiographic manifestation of hyperkalemia is an increase in the rate of ventricular repolarization, which results in a peaking of the T wave at serum potassium concentrations of ~5.5 to 6 mEq/L (~5.5–6 mmol/L) *(B)*, relative to the normal ECG presentation *(A)*. Further increases in the serum potassium concentration above 6 mEq/L (6 mmol/L) result in conduction delays through the His-Purkinje system, the atrial myocardium, and the ventricular myocardium. The ECG manifestations of these conduction delays and the sequence in which they occur are a widening of the PR interval *(C)*, delay through the His-Purkinje system, a loss of the P wave *(D)*, delay through the atrial myocardium, a widening of the QRS complex *(E)*, and delay through the ventricular myocardium. Finally, there is a merging of the QRS complex with the T wave *(F)*, which results in a sine-wave appearance.

TREATMENT

Hyperkalemia

DESIRED OUTCOME

The goals of therapy for the treatment of hyperkalemia are to antagonize adverse cardiac effects, reverse signs and symptoms that are present, and return the serum and total-body stores of potassium to normal. The design of the treatment approach is determined by the severity of hyperkalemia, the rapidity of its development, and the patient's clinical condition. Although ECG changes are directly proportional to the plasma potassium concentration and its rate of increase, they may not be present in all patients. In contrast, ventricular fibrillation may be the first cardiac manifestation of hyperkalemia in some patients.[24] Asymptomatic patients with mild hyperkalemia usually require no specific therapy other than dietary education to control intake, and monitoring of serum potassium daily if an inpatient or weekly if an outpatient to assure resolution. Severe hyperkalemia (>7 mEq/L [>7 mmol/L]) or moderate hyperkalemia (6.0–6.9 mEq/L [6.0–6.9 mmol/L]), when associated with clinical symptoms or ECG changes, requires immediate treatment. Initial treatment of severe and moderate symptomatic hyperkalemia is focused on antagonism of the cardiac membrane actions of hyperkalemia (e.g., with calcium). Secondarily, one should attempt to decrease extracellular potassium concentration by promoting its intracellular movement (e.g., with glucose, insulin, β_2-receptor agonists, or sodium bicarbonate) or enhance its removal from the body by hemodialysis, the oral administration of cation-exchange resins, and/or the use of loop diuretics. In any case, the underlying cause of hyperkalemia should be identified and reversed, and exogenous potassium must be withheld.

GENERAL APPROACH TO TREATMENT

A general treatment approach for patients with hyperkalemia is outlined in Figure 60–2. In patients who have acute ECG changes, IV calcium should be administered to prevent or treat any cardiac manifestations of hyperkalemia. At the same time, the serum potassium concentration should be rapidly decreased to <5.0 mEq/L (<5.0 mmol/L) within minutes by administering drugs that cause an intracellular shift, followed by those that increase the elimination of potassium from the body.[24] If the patient is asymptomatic, rapid correction may not be necessary, and will likely depend on the clinical context associated with the rise in serum potassium concentration. If one anticipates the need to reduce total-body potassium stores, an ion exchange resin (e.g., sodium polystyrene sulfonate [SPS]) that results in removal of potassium from the body over several hours to days should be initiated shortly after the emergent care has been instituted.

NONPHARMACOLOGIC THERAPY

A recent study suggested that hemodialysis patients who ingested foods supplemented with glycyrrhetinic acid, the active ingredient in licorice, were better able to maintain plasma potassium concentrations within the normal range compared to hemodialysis patients given placebo.[25,26] Glycyrrhetinic acid inhibits the enzyme 11β-hydroxy-steroid dehydrogenase II, thereby increasing cortisol availability in the colon. The net result is enhanced potassium elimination in the feces. Other nonpharmacologic therapies, specifically available for dialysis-dependent patients with end-stage renal disease (ESRD), are the institution of intermittent dialysis or hemofiltration therapy.

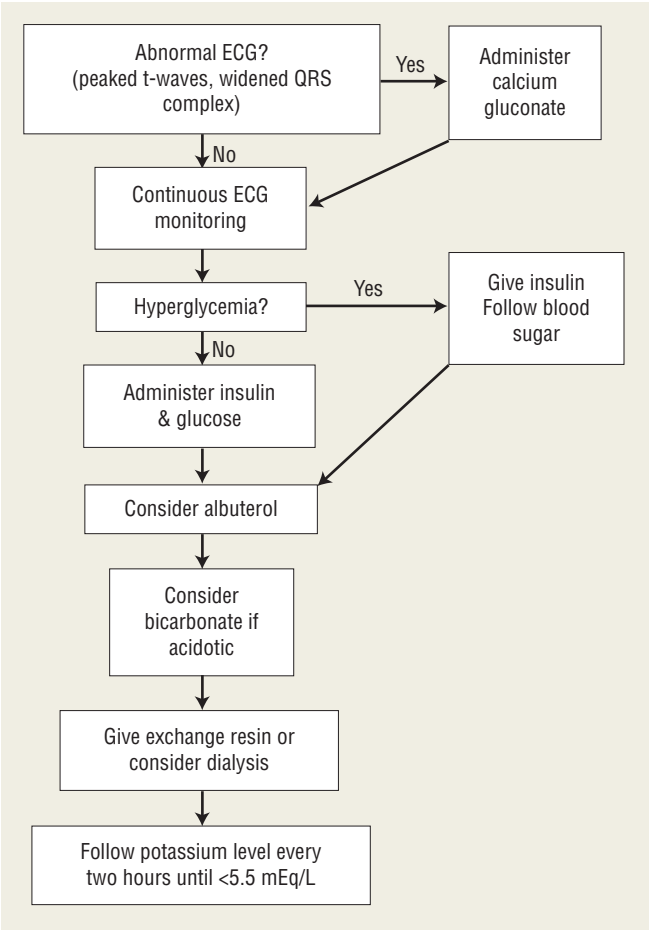

FIGURE 60-2. Treatment approach for hyperkalemia. (Serum potassium of 5.5 mEq/L is equivalent to 5.5 mmol/L.)

PHARMACOLOGIC THERAPY

Various drug therapies have been used to lower the serum potassium concentration. The optimal regimen for a given patient is dependent on the rapidity and degree of lowering that is necessary. Table 60–5 provides an overview of the available therapies, and their respective onset and duration of action one can expect.

While specific treatment recommendations vary, it is generally accepted that asymptomatic patients with potassium concentrations <6.0 mEq/L (<6.0 mmol/L) can be treated conservatively. In patients with normal renal function, or those with stage 3 or 4 CKD, this typically involves the administration of furosemide to promote urinary potassium excretion. When given IV at a dosage of 40 to 80 mg, urine flow usually increases within minutes and persists for approximately 4 to 6 hours. Close monitoring of the patient's volume status and other electrolyte concentrations is required while the patient is receiving furosemide or other loop diuretic therapy. Alternatively, SPS (Kayexalate) a cation-exchange resin can be administered orally or rectally by enema. SPS is available in powder form or prepackaged as a 33% sorbitol suspension. The oral route is more effective than the enema and is better tolerated by the patient. As the resin passes through the intestines, each gram of SPS exchanges 1 mEq (1 mmol) of sodium for 1 mEq (1 mmol) of potassium ions, which are in a relatively higher concentration in the large intestine. The onset of action of SPS is within 1 hour, and it can be repeated every 4 hours as needed. The sorbitol component of the suspension promotes the excretion of the cationically modified potassium exchange resin by inducing diarrhea. The usual oral SPS dose is 15 to 60 g in the 33% sorbitol suspension. A retention enema prepared by mixing 60 to 100 g SPS in 100 to 200 mL of a 30% sorbitol or 10% dextrose suspension warmed to body temperature will usually remove 0.5 mEq of potassium per gram of SPS.[27] The enema may be retained in the rectum for several hours as tolerated by the patient.

In symptomatic patients, or in those with severe hyperkalemia, emergency care is indicated. Initial therapy in this setting is the administration of IV calcium chloride or gluconate 1 g to protect the heart from life-threatening arrhythmias.[24] Calcium antagonizes the cardiac membrane effect of hyperkalemia by reducing the electrical threshold potential for cardiac myocytes and reverses ECG changes within minutes. Its duration of action is 30 to 60 minutes, and it can be repeated as needed based on ECG findings. Intravenous calcium can be given as either the chloride or gluconate salt; each is available as a 10% solution by weight. Calcium chloride provides approximately three times more calcium than equal volumes of the gluconate salt; however, it can cause tissue necrosis if extravasation occurs. For this reason, calcium gluconate is more commonly administered, with the standard dose being 10-mL IV bolus over 5 to 10 minutes.

Rapid correction of hyperkalemia may necessitate the administration of drugs that result in an intracellular shift of potassium, such as insulin and dextrose, sodium bicarbonate, and a β_2-adrenergic receptor agonist (e.g., albuterol or terbuatline). The treatment of choice depends on the underlying medical disorders accompanying hyperkalemia. For example, in patients with concomitant metabolic acidosis, a sodium bicarbonate bolus or infusion of 50 to 100 mEq (50–100 mmol) is the preferred therapy (see Chapter 61 for additional information). Sodium bicarbonate helps to correct the metabolic acidosis by raising the extracellular pH, in addition to causing a rapid intracellular potassium shift. It should be noted that sodium bicarbonate is much less effective when hyperkalemia is not related

TABLE 60-5 Therapeutic Alternatives for the Management of Hyperkalemia

Medication	Dose	Route of Administration	Onset/Duration of Action	Acuity	Mechanism of Action	Expected Result
Calcium	1 g	IV over 5–10 min	1–2 min/10–30 min	Acute	Raises cardiac threshold potential	Reverses electrocardiographic effects
Furosemide	20–40 mg	IV	5–15 min/4–6 h	Acute	Inhibits renal Na^+ reabsorption	Increased urinary K^+ loss
Regular insulin	5–10 units	IV or SC	30 min/2–6 h	Acute	Stimulates intracellular K^+ uptake	Intracellular K^+ redistribution
Dextrose 10%	1,000 mL (100 g)	IV over 1–2 h	30 min/2–6 h	Acute	Stimulates insulin release	Intracellular K^+ redistribution
Dextrose 50%	50 mL (25 g)	IV over 5 min	30 min/2–6 h	Acute	Stimulates insulin release	Intracellular K^+ redistribution
Sodium bicarbonate	50–100 mEq (50–100 mmol)	IV over 2–5 min	30 min/2–6 h	Acute	Raises serum pH	Intracellular K^+ redistribution
Albuterol	10–20 mg	Nebulized over 10 min	30 min/1–2 h	Acute	Stimulates intracellular K^+ uptake	Intracellular K^+ redistribution
Hemodialysis	4 h	N/A	Immediate/variable	Acute	Removal from serum	Increased K^+ elimination
Sodium polystyrene sulfonate	15–60 g	Oral or rectal	1 h/variable	Nonacute	Resin exchanges Na^+ for K^+	Increased K^+ elimination

K^+, potassium ion; Na^+, sodium ion; SC, subcutaneous.

to metabolic acidosis.[21] Sodium bicarbonate is also less effective in patients with ESRD, in whom a decrease in serum potassium may not be seen for as long as 4 hours.[27] Sodium bicarbonate can also lead to sodium and volume overload in patients with stage 4 or 5 CKD. Administration of a fast-acting (e.g., Insulin Lispro) or regular insulin (5–10 units IV and dextrose (10% or 50%) is an effective method of reducing potassium. Insulin increases the activity of the Na^+-K^+-ATPase pump, thereby intracellularly shifting potassium. Glucose should be given with insulin unless the serum glucose is >250 mg/dL (>13.9 mmol/L) because hypoglycemia can develop as a result of the effects of the insulin therapy. An IV bolus of 10 units of regular insulin and 25 g of dextrose usually lowers the serum potassium concentration by 0.6 mEq/L (0.6 mmol/L) in dialysis-dependent patients.[24] β_2-Adrenergic agonists have a dual mechanism for lowering serum potassium. First, they stimulate the Na^+-K^+-ATPase pump to promote intracellular potassium uptake. Second, they stimulate pancreatic β-receptors to increase insulin secretion. Albuterol can be administered via IV (0.5 mg given over 15 minutes) or via nebulizer (10–20 mg nebulized over 10 minutes); however, it should be noted that injectable albuterol is not available in the United States. In ESRD patients, decreases in plasma potassium concentration of 0.6 mEq/L (0.6 mmol/L) and 1.0 mEq/L (1.0 mmol/L) can be anticipated after inhalation of 10 mg and 20 mg of albuterol, respectively. Of note, the doses of inhaled albuterol used for hyperkalemia are at least 4 times higher than those typically used for bronchospasm.[24] There are important limitations with albuterol therapy, most notably variable bioavailability via the inhaled route (leading to potential over- or under-dosing and unpredictability of response) and second, cardiac side effects such as tachycardia which are undesirable in patients who already have an abnormal ECG. Furthermore, as many as 40% of patients may be resistant to the hypokalemic effects of albuterol and patients already receiving a nonselective β_2-receptor antagonist may not respond. Therefore, albuterol should not be used alone for the urgent treatment of hyperkalemia in CKD patients.[24] The use of subcutaneous terbutaline in a small group of dialysis patients with hyperkalemia has also been shown to be effective.[28]

A Cochrane Review evaluated the emergency treatment of hyperkalemia.[29] Many of the reviewed studies were small, and not all intervention groups had sufficient data for meta-analysis to be performed. However, given these limitations, inhaled and nebulized β-agonists, and IV insulin-and-glucose were all deemed effective. The combination of nebulized β-agonists with IV insulin and glucose appeared to be more effective than either agent alone. The meta-analysis results were equivocal for IV bicarbonate, and notably, SPS was not effective by 4 hours.

A major problem with drawing conclusions from this meta-analysis is the heterogeneity of the study population. Most of the data were from nonrandomized, noncontrolled observational studies and case reports. Doses of the drugs were not standardized and follow-up was often lacking. Therefore, the clinician should exercise caution when extrapolating these findings to his or her clinical practice. This underscores the need for clinicians to be able to interpret the limitations of the published literature. Nonetheless, the Cochrane database review corroborates the approach detailed in Figure 60–2.

CLINICAL CONTROVERSY

SPS suspension pre-mixed in 33% sorbitol is commonly stocked in hospital pharmacies for the management of hyperkalemia, however, its clinical effectiveness is now being reconsidered.[29] More important, emerging data suggest its use may be associated with GI necrosis.[30–31] Clinicians should reserve SPS use until other alternative treatments have failed.

EVALUATION OF THERAPEUTIC OUTCOMES

The evaluation of therapeutic outcomes differs based on the severity of hyperkalemia. For example, mild or moderate asymptomatic hyperkalemia is observed much more frequently compared with symptomatic, severe hyperkalemia. Many drugs such as ACEIs, ARBs, and spironolactone result in asymptomatic hyperkalemia. In patients with normal renal function, once these drugs are initiated and the dose titrated, clinicians should check the potassium concentration at least monthly. For those patients with renal dysfunction, monitoring should be more frequent, such as biweekly until the dose is stabilized. In the case where the patient has been on a stable dose for a long period of time and hyperkalemia develops, the clinician should attempt to downward titrate the dose or switch to another medication without hyperkalemia as a side effect (e.g., calcium channel blocker).

In patients who have acute symptomatic hyperkalemia (e.g., ECG changes), frequent potassium concentration and ECG monitoring is warranted. The patient should receive continuous ECG telemetry monitoring until the serum potassium concentration decreases below 5.0 mEq/L (5.0 mmol/L), and the ECG abnormalities resolve. Similarly, while the patient is receiving emergent therapy, serial serum potassium concentrations should be obtained hourly until the potassium concentration decreases below 5.0 mEq/L (5.0 mmol/L). For patients who receive insulin and dextrose therapy for hyperkalemia, blood glucose monitoring should be performed hourly, or more frequently if patients demonstrate signs and symptoms of hypoglycemia. For patients who receive large doses of sodium bicarbonate therapy for hyperkalemia, an arterial blood gas or serum chemistry profile should be obtained to assess their acid–base status. Furthermore, the patient should be evaluated for signs of fluid overload secondary to the high sodium load. Patients receiving albuterol or terbutaline therapy should be questioned regularly regarding the development of palpitations and tachycardia. The patient's medication records should be reviewed to assure the patient is not receiving drug therapy that increases the serum potassium concentration. Furthermore, the patient should be questioned regarding the occurrence of diarrheal stool output.

DISORDERS OF MAGNESIUM HOMEOSTASIS

7 Magnesium plays a central role in cellular function and is an important cofactor in more than 300 biochemical reactions in the body, especially those systems that are dependent on adenosine triphosphate. Mitochondrial function, protein synthesis, cell membrane function, parathyroid hormone (PTH) secretion, and glucose metabolism are just a few important functions affected by magnesium.[32] It is the fourth most abundant extracellular cation and second most abundant intracellular cation, after potassium. Disorders of magnesium homeostasis are commonly encountered in clinical situations and most frequently are manifested as alterations in cardiovascular and neuromuscular function. Life-threatening conditions such as paralysis and cardiac arrhythmias can occur, making the proper recognition and treatment of these problems of paramount importance. Altered magnesium balance also plays a key role in chronic disease states such as diabetes mellitus, chronic kidney disease, osteoporosis, development of kidney stones, as well as heart and vascular disease.[33]

8 Magnesium is principally distributed in bone (67%) and muscle (20%). Because of its predominantly intracellular distribution, measurement of magnesium in the extracellular compartment may not accurately reflect the total-body magnesium content. The

majority of magnesium in the extracellular fluid is in the ionized form as only 20% is bound to serum proteins. The normal range for serum magnesium is 1.4 to 1.8 mEq/L, which is equivalent to 1.7 to 2.3 mg/dL or 0.70 to 0.95 mmol/L.[33,34]

The recommended daily dietary magnesium intake for adults is approximately 420 mg/day and 320 mg/day for men and women, respectively.[33] The maintenance of magnesium homeostasis depends on the balance between intake and output. Thirty percent to 40% of ingested magnesium is absorbed in the small bowel. The absorption of magnesium decreases as the dietary intake increases. Reductions in absorption have also been noted in the elderly and those with CKD. A small amount is present in intestinal secretions and reabsorbed in the sigmoid colon. The kidneys play a major role in maintaining magnesium balance. Approximately 95% of the filtered magnesium is reabsorbed, thus in most patients less than 5% is excreted in the urine.[34] Renal magnesium handling is unique in that approximately 20% of the filtered magnesium is reabsorbed in the proximal tubule; the majority of reabsorption occurs in the thick ascending limb of the loop of Henle. This explains why loop diuretics often cause profound urinary magnesium wasting. Unlike most other important electrolytes, there is no hormonal regulation of the distribution of magnesium between bone and circulating or intracellular magnesium pools. Because of this, both hypomagnesemia and hypermagnesemia commonly occur.

HYPOMAGNESEMIA

Epidemiology

Hypomagnesemia is a common problem in both ambulatory and hospitalized patients. Although the exact prevalence is difficult to estimate, it has been reported that up to 65% of intensive care unit patients are magnesium deficient.[35] Although serum magnesium concentrations are not a reliable index of total-body magnesium content, they remain the primary diagnostic tool to evaluate body stores.

Etiology and Pathophysiology

9 Hypomagnesemia is usually associated with disorders of the intestinal tract or kidney.[34] Drugs or conditions that interfere with intestinal absorption or increase renal excretion of magnesium can result in hypomagnesemia (Table 60–6). Decreased intestinal absorption as a result of small bowel disease is the most common cause of hypomagnesemia worldwide. These disorders include regional enteritis; radiation enteritis; ulcerative colitis; acute and chronic diarrhea; pancreatic insufficiency and other malabsorptive syndromes; small-bowel bypass surgery; and chronic laxative abuse. Hypomagnesemia is commonly associated with alcoholism. The etiology is often multifactorial, including reduced intake, pancreatic insufficiency, chronic vomiting and diarrhea, and urinary magnesium wasting. In addition, patients who are hospitalized for acute alcohol withdrawal often receive IV glucose and can experience even greater reductions in their serum magnesium concentration.

Primary renal magnesium wasting can be caused by a defect in renal tubular magnesium reabsorption, or inhibition of sodium reabsorption in those segments in which magnesium transport follows passively. The former condition is associated with hypercalciuria, nephrolithiasis, and progressive renal disease. The latter is associated with Gitelman's and Bartter's syndromes.[34] Much more common than these is renal magnesium wasting secondary to thiazide and loop diuretics.[33] Other commonly used drugs that can cause renal magnesium wasting include aminoglycosides, amphotericin B, cyclosporine, digoxin, tacrolimus, cisplatin, pentamidine, and foscarnet.

TABLE 60-6 Causes of Hypomagnesemia

Gastrointestinal
Reduced intake
Protein-calorie malnutrition
Prolonged parenteral fluid administration without magnesium
Alcoholism
Reduced absorption
Primary hypomagnesemia
Malabsorption syndromes (e.g., tropical sprue, celiac disease, radiation enteritis, or intestinal lymphectasia)
Short-bowel syndrome (e.g., small-bowel resection or ileal bypass)
Pancreatic insufficience
Increased loss
Excessive vomiting
Prolonged nasogastric suction
Excessive laxative use
Intestinal and biliary fistulas
Prolonged diarrhea (ulcerative colitis, Crohn disease, or cancer of the colon)
Renal
Primary tubular disorders
Primary renal magnesium wasting
Bartter's syndrome
Renal tubular acidosis
Diuretic phase of acute tubular necrosis
Postobstructive diuresis
Postrenal transplant diuresis
Glomerulonephritis
Pyelonephritis
Drug-induced renal losses
Aminoglycosides
Amphotericin B
Cyclosporine
Tacrolimus
Diuretics
Digitalis
Cisplatin
Pentamidine
Forscarnet
Hormone-induced renal losses
Primary hyperparathyroidism
Hyperthyroidism
Aldosteronism
"Hungry bone syndrome" after parathyroidectomy
Internal redistribution
Diabetic ketoacidosis
Glucose, amino acid, or insulin administration
Massive blood transfusion (citrate)
Pancreatitis with lipidemia (magnesium soap)
Other
Excessive sweating and lactation
Hypercalcemia and hypercalciuria
Phosphate depletion
Chronic alcoholism
Extracellular fluid volume expansion

CLINICAL PRESENTATION OF HYPOMAGNESEMIA

General

- The dominant organ systems affected by hypomagnesemia are the neuromuscular and cardiovascular systems.

Symptoms

- Neuromuscular symptoms such as tetany, twitching, and generalized convulsions are common.
- Cardiac symptoms include heart palpitations.

Signs

- Neuromuscular: Presence of Chvostek's sign, Trousseau's sign, tremor, and tetany.
- Cardiovascular: Cardiac arrhythmias (ventricular fibrillation, torsade de pointes, or digoxin-induced arrhythmias), sudden cardiac death, and hypertension can be present. ECG abnormalities include widened QRS complex and peaked T waves with mild hypomagnesemia; and prolonged PR interval, progressive widening of QRS complex, and flattened T waves with moderate to severe hypomagnesemia.

Laboratory Tests

- Serum magnesium concentration less than 1.4 mEq/L (0.70 mmol/L). Serum potassium and calcium concentrations can also be low.

TREATMENT

Hypomagnesemia

DESIRED OUTCOME

The treatment goals in the management of hypomagnesemia are (1) resolution of the corresponding signs and symptoms, (2) restoration of normal magnesium concentrations, (3) correction of concomitant electrolyte abnormalities, and (4) identification and correction of the underlyingcause of magnesium depletion.

GENERAL APPROACH TO TREATMENT

Nearly all of the data regarding magnesium replacement therapy have been derived from reports in acutely ill, hospitalized patients. Magnesium supplementation can be given by the oral, IM, or IV route. Table 60–7 outlines one approach to the hypomagnesemic patient. The severity of the magnesium depletion and the presence of severe signs and symptoms should dictate the route of administration. Because IM administration is painful, it should be reserved for those patients with severe hypomagnesemia and limited venous access. IV bolus administration is associated with flushing, sweating, and a sensation of warmth; thus bolus administration should be avoided if possible. Additionally, because calcium forms a complex with the sulfate moiety, which is then excreted, large amounts of IV magnesium sulfate should be administered with caution to hypocalcemic patients, as it can further exacerbate calcium deficiency.[33] There have been no clinical trials assessing the optimal regimen for magnesium replacement, however, it is widely accepted that 8 to 12 g of magnesium sulfate be administered in the first 24 hours followed by 4 to 6 g per day for 3 to 5 days to adequately replete body stores.[35] Even if severe magnesium depletion is present, approximately 50% of the administered dose is excreted in the urine. Consequently, magnesium replacement should be performed over 3 to 5 days, and continued supplementation should be provided for patients unable to eat and for those patients with continued magnesium wasting. Table 60–8 lists the commonly prescribed magnesium oral supplements and their respective elemental magnesium content.

TABLE 60-7 Guidelines for Treatment of Magnesium Deficiency in Adults

1. Serum magnesium <1 mEq/L (<1.2 mg/dL [<0.5 mmol/L]) with life-threatening symptoms (seizure or arrhythmia)
Day 1
2 g magnesium sulfate (1 g magnesium sulfate = 8.1 mEq Mg^{2+}) mixed with 6 mL 0.9% NaCl in 10-mL syringe and administer IV push over 1 min
Follow with 1.0 mEq Mg^{2+}/kg lean body weight IV infusion over 24 h
Days 2–5
0.5 mEq [0.25 mmol] Mg^{2+}/kg lean body weight per day divided in maintenance IV fluids
2. Serum magnesium <1 mEq/L (<1.2 mg/dL [<0.5 mmol/L]) without life-threatening symptoms
Day 1
Total of 1 mEq (0.5 mmol) Mg^{2+}/kg lean body weight per day as continuous IV infusion, or divided and given IM q 4 h for five doses
Days 2–5
0.5 mEq (0.25 mmol) Mg^{2+}/kg lean body weight IV infusion per day as continuous IV infusion or divided and given IM every 6–8 h
3. Serum magnesium >1 mEq/L (>1.2 mg/dL [>0.5 mmol/L]) and <1.5 mEq/L (<1.8 mg/dL [<0.75 mmol/L]) without symptoms
As in no. 2 above, or
Milk of magnesia 5 mL 4 times daily as tolerated, or
Magnesium-containing antacid 15 mL 3 times daily as tolerated, or
Magnesium oxide tablets 400 mg 4 times daily; increase to two tablets 4 times daily as tolerated

Mg^{2+}, magnesium ion; NaCl, sodium chloride.

TABLE 60-8 Common Magnesium Products and Their Elemental Magnesium Content

Product	Elemental Magnesium Content
Magnesium oxide	242 mg in a 400-mg tablet
Magnesium hydroxide	167 mg in a 400-mg tablet or 5-mL oral suspension
Magnesium citrate	48 mg in the 290 mg/5 mL oral solution
Magnesium gluconate	27 mg in a 500-mg tablet
Magnesium lactate	84 mg in a 84 mg-tablet

PHARMACOLOGIC THERAPY

It is currently controversial whether all asymptomatic patients require magnesium supplementation.[34] However, should treatment be warranted, those patients with serum magnesium concentrations greater than 1 mEq/L (1.2 mg/dL [0.5 mmol/L]), can be treated with oral supplements, such as magnesium-containing antacids or laxatives, or magnesium oxide tablets or capsules. The typical dose of magnesium oxide is 400 (242 mg elemental magnesium) to 800 mg (484 mg elemental magnesium) given 3 or 4 times daily until repleted. However, as expected, diarrhea is the most common dose-limiting side effect of oral therapy, which can greatly reduce patient compliance. Moreover, many oral products contain very little magnesium, which necessitates frequent dosing (Table 60–8).

In cases of severe magnesium depletion (serum concentrations <1 mEq/L [<0.5 mmol/L]), or if signs and symptoms are present regardless of the serum concentration, IV magnesium should be administered. A 50% solution of magnesium sulfate is available for injection in 2-mL or 10-mL ampules (4 mEq/mL [2 mmol/mL]). The 50% solution should be diluted to 20% before injection to prevent venous sclerosis and pain. Therapy should be continued until the signs and symptoms have completely resolved. In patients with renal insufficiency, the dose should be reduced by 50%.

EVALUATION OF THERAPEUTIC END POINTS

In patients with acute, asymptomatic mild to moderate hypomagnesemia receiving therapy, serum magnesium concentrations should be obtained at least daily during their hospitalization.

Patients receiving oral magnesium therapy should be questioned regarding GI tolerance and the occurrence of diarrhea. Patients being treated for symptomatic severe hypomagnesemia should have their serum magnesium concentration monitored hourly until the serum concentration reaches 1.5 mEq/L (0.75 mmol/L) and the symptoms resolve. At that point, the serum magnesium concentration can be monitored every 6 to 12 hours for the next 24 hours while receiving magnesium supplementation. Once the magnesium concentration is stable in the normal range, a concentration can be obtained daily. It should be reiterated that it typically takes 3 to 5 days to fully replete total-body magnesium stores. Patients receiving oral magnesium-containing antacids or supplements should be asked regularly about the occurrence of diarrhea.

HYPERMAGNESEMIA

Epidemiology

⑩ Hypermagnesemia (serum magnesium >2 mEq/L [>1.0 mmol/L]) is a rare occurrence that is generally seen in patients with stage 4 or 5 CKD when magnesium intake exceeds the excretory capacity of the kidneys. Elderly patients are prone to hypermagnesemia because of their reduced glomerular filtration rate (GFR) and because of their tendency to consume magnesium-containing antacids and vitamins.

Etiology and Pathophysiology

Because absolute magnesium excretion decreases as GFR declines, serum magnesium concentrations tend to increase in patients with moderate to severe CKD. Indeed, magnesium concentrations steadily increase as the GFR decreases below 30 mL/min/1.73m^2 (0.29 mL/s/m^2). As long as the patient maintains a normal diet, the serum magnesium concentration typically stabilizes at approximately 2.5 mEq/L (1.25 mmol/L). If patients with stage 4 or 5 CKD are taking concomitant magnesium-containing antacids, the serum concentration can approach 6 mEq/L (3 mmol/L), a value associated with signs and symptoms of toxicity. Critically ill patients with multiorgan system failure receiving enteral or parenteral nutrition are also prone to develop hypermagnesemia. Finally, the parenteral treatment of eclampsia with magnesium sulfate can lead to hypermagnesemia. Table 60–9 lists other causes of hypermagnesemia.

Clinical Presentation

The signs and symptoms of hypermagnesemia reflect magnesium's action on the neuromuscular and cardiovascular systems.[35,36] The main symptoms include lethargy, confusion, arrhythmias, and muscle weakness. Symptoms are rare when the serum concentration is <4 mEq/L (<2 mmol/L) (Fig. 60–3).

TABLE 60-9 Causes of Hypermagnesemia

Decreased renal excretion
Acute renal failure
Chronic kidney disease with exogenous intake
Excessive intake
Treatment of toxemia of pregnancy
Ureteral irrigants (hemiacidrin)
Cathartics
Other
Lithium therapy
Hypothyroidism
Milk-alkali syndrome
Addison disease
Viral hepatitis
Acute diabetic ketoacidosis

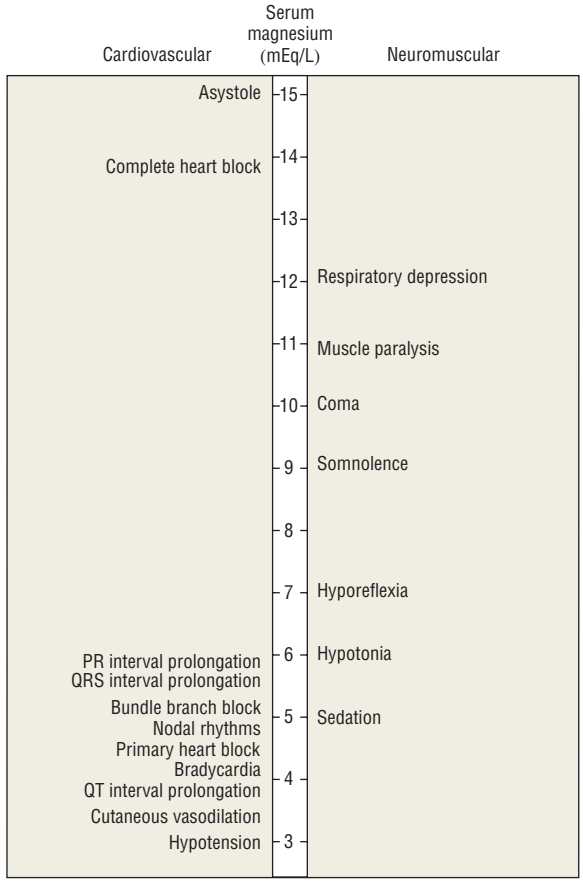

FIGURE 60-3. Clinical findings associated with hypermagnesemia. (Serum magnesium levels in mmol/L can be determined by multiplying the serum magnesium value expressed in mEq/L by 0.5.)

TREATMENT

Hypermagnesemia

DESIRED OUTCOME

The goals of therapy are to (1) reverse the neuromuscular and cardiovascular manifestations of hypermagnesemia, (2) decrease the magnesium concentration toward normal values, and (3) identify and treat the underlying cause of hypermagnesemia.

PHARMACOLOGIC THERAPY

There are three primary means of treating hypermagnesemia: (1) reduce magnesium intake, (2) enhance elimination of magnesium, and (3) antagonize the physiologic effects of magnesium. The optimal treatment regimen for the management of hypermagnesemia depends on the severity of the patient's signs and symptoms and the degree of serum concentration elevation. Intravenous elemental calcium doses of 100 to 200 mg directly antagonize the neuromuscular and cardiovascular effects of hypermagnesemia. Oral calcium is not effective because of its relatively poor bioavailability and slow onset of action. The clinical effect of calcium is immediate, but the effect is transient; hence, repeated IV doses of 100 to 200 mg of elemental calcium (e.g., 2 g of calcium gluconate) might need to be administered hourly until the signs or symptoms abate and the magnesium concentration

TABLE 60-10 Magnesium Content of Selected Foods

Food	Elemental Magnesium Content (mg)
Halibut, cooked, 3 oz	90
Almonds, dry roasted, 1 oz	80
Cashews, dry roasted, 1 oz	75
Spinach, one-half cup	75
Shredded wheat cereal, two biscuits	55
Instant oatmeal, 1 cup	55
Baked potato with skin (medium)	50
Peanuts, dry roasted, 1 oz	50
Yogurt, plain, skim milk, 8 oz	45
Brown rice, long-grained, one-half cup	40
Banana (medium)	30

is normalized. Supportive care with cardiac pacing, vasopressors, and mechanical ventilation can be necessary in life-threatening situations. In patients with normal renal function, or those with stage 1, 2, or 3 CKD, forced diuresis with saline and loop diuretics can promote magnesium elimination. An initial IV bolus of furosemide 40 mg or a similar equivalent can be used. Subsequent dosing can be determined based on the patient's clinical response. Patients with CKD can require long-term loop diuretic therapy to maintain adequate fluid and electrolyte balance. In dialysis patients, their hemodialysis prescription should be changed to employ magnesium-free dialysate.

EVALUATION OF THERAPEUTIC END POINTS

Patients who are receiving IV calcium salts for the treatment of severe, symptomatic hypermagnesemia should have their serum magnesium concentration evaluated hourly until symptoms abate and the magnesium concentration decreases below 4 mg/dL (1.64 mmol/L). Furthermore, the patient should be continuously monitored to detect ECG changes. In CKD patients who can produce urine, forced diuresis with saline and furosemide should reduce the serum magnesium concentration within 6 to 12 hours. Close monitoring of the urine output and physical examination for signs of volume overload are important. Emergency hemodialysis will usually correct the hypermagnesemia within 4 hours and is a reasonable option for those who are currently receiving hemodialysis. To prevent further episodes of hypermagnesemia, the patient should receive dietary education regarding foods and beverages that contain large quantities of magnesium (Table 60–10).

In conclusion, disorders of potassium and magnesium are frequently encountered in both the acute care and community ambulatory care settings. If severe, these disorders can have catastrophic results. Clinicians should be able to identify patients at risk for these common electrolyte disorders and quickly design appropriate pharmacotherapy and monitoring regimens to optimize patient outcomes.

ABBREVIATIONS

ACEI: angiotensin-converting enzyme inhibitor

AKI: acute kidney injury

ARB: angiotensin-II receptor blocker

CKD: chronic kidney disease

ECG: electrocardiogram

ESRD: end-stage renal disease

GI: gastrointestinal

IV: intravenous

NSAID: nonsteroidal anti-inflammatory drug

PTH: parathyroid hormone

SPS: sodium polystyrene sulfonate

CHAPTER 61

Acid–Base Disorders

JOHN W. DEVLIN AND GARY R. MATZKE

KEY CONCEPTS

1. The kidney plays a central role in the regulation of acid–base homeostasis through the excretion or reabsorption of filtered bicarbonate (HCO_3^-), the excretion of metabolic fixed acids, and generation of new HCO_3^-.
2. Metabolic acidosis and metabolic alkalosis are generated by a primary change in the serum bicarbonate concentration. In metabolic acidosis, bicarbonate is lost or a nonvolatile acid is gained, whereas metabolic alkalosis is characterized by a gain in bicarbonate or a loss of nonvolatile acid.
3. Arterial blood gases, along with serum electrolytes, physical findings, medical and medication history, and the clinical condition of the patient, are the primary tools to determine the cause of an acid–base disorder and to design and monitor a course of therapy.
4. Renal tubular acidosis refers to a group of disorders characterized by impaired tubular renal acid handling despite normal or near-normal glomerular filtration rates. These patients often present with hyperchloremic metabolic acidosis.
5. Respiratory compensation for a primary metabolic acidosis begins rapidly (within 15–30 minutes) but does not reach a steady state for 12 to 24 hours after the onset of metabolic acidosis.
6. Primary therapy of most acid–base disorders must include treatment or elimination of the underlying cause, not just correction of the pH and electrolyte disturbances.
7. Potassium supplementation is always necessary for patients with chronic metabolic acidosis, as the bicarbonaturia resulting from alkali therapy increases renal potassium wasting.
8. Effective treatment of the underlying cause of some organic acidoses (e.g., ketoacidosis) can result in the regeneration of bicarbonate within hours, thus mitigating the need for alkali therapy.
9. Loss of gastric acid from vomiting or nasogastric suctioning is often responsible for the development of a metabolic alkalosis, characterized by hypochloremia and hyperbicarbonatemia.
10. Aggressive diuretic therapy can produce a metabolic alkalosis, and the accompanying hypokalemia can be serious.
11. The patient's response to volume replacement can be predicted by the urine chloride concentration and permits the differential diagnosis of metabolic alkalosis.
12. Management of sodium chloride-resistant metabolic alkaloses usually consists of treatment of the underlying cause of mineralocorticoid excess. In patients in whom the mineralocorticoid excess cannot be corrected, chronic pharmacologic therapy can be required.
13. In most cases of acute metabolic acidosis, such as following cardiopulmonary arrest, sodium bicarbonate therapy is not indicated and can be detrimental. Blood gas analysis should guide therapy.

Acid–base disorders are common and often serious disturbances that can result in significant morbidity and mortality. This chapter reviews the mechanisms responsible for the maintenance of acid–base balance and the laboratory analyses that aid clinicians in their assessment of acid–base disorders. The pathophysiology of the four primary acid–base disturbances is presented, the therapeutic options are critiqued, and guidelines for the achievement of the desired therapeutic outcomes are presented. Because many drugs affect acid–base homeostasis and many acid–base abnormalities are potentially preventable, clinicians must anticipate drug-related problems to avoid or minimize the clinical consequences of acid base disorders, and when necessary, design appropriate treatment regimens.

ACID–BASE CHEMISTRY

An acid (in this equation, hydrochloric acid) is a substance that can *donate* protons (hydrogen ion [H^+]):

$$\text{(acid) } HCl \rightarrow H^+ + \text{chloride ion } (Cl^-)$$

A base (in this equation, ammonia [NH_3]) is a substance that can *accept* protons (hydrogen ion [H^+]):

$$\text{Ammonia } (NH_3) + H^+ \rightarrow NH^+_4 \text{ (base)}$$

The acid–base pairs commonly encountered in clinical practice are listed in Table 61–1.

TABLE 61-1 Acid–Base Pairs

Carbonic acid/bicarbonate	H_2CO_3/HCO_3^-
Monobasic/dibasic phosphate	$H_2PO_4^-/HPO_4^-$
Ammonium/ammonia	NH_4^+/NH_3
Lactic acid/lactate	$H_6C_3O_2/H_5C_3O_2^-$

The acidity of body fluids is quantified in terms of the hydrogen ion concentration. By convention, the degree of acidity is expressed as pH, or the negative logarithm (base 10) of the hydrogen ion concentration. Thus hydrogen ion concentration and pH are inversely related. Normally, the pH of blood is maintained at 7.40 ($[H^+]$ of 4×10^{-8} M) with a range of 7.35 to 7.45. A pH of less than 6.7 ($[H^+]$ of 2×10^{-7} M), representing a five-fold increase in hydrogen ion concentration, or greater than 7.7 ($[H^+]$ of 2×10^{-8} M), representing a 50% decrease in hydrogen ion concentration, are considered incompatible with life.

The hydrogen ion concentration in blood may not be indicative of that in other body compartments. For example, the pH within cells, within the cerebrospinal fluid, or on the surface of bone can all be altered without causing an alteration in blood pH.[1] Recognizing this caveat, the acid–base status of the body is usually analyzed based on measurement of blood pH. Alterations in blood pH serve as the basis for the diagnosis of acid–base disorders.

Because the dissociation of acid–base pairs is an equilibrium reaction, the relationship between hydrogen ion concentration or pH and the relative concentrations of the acid and base can be described mathematically in terms of the dissociation constant for the acid–base buffer pair. When expressed as a logarithmic relationship, where p*K* is the negative logarithm of the dissociation constant *K*, this is known as the Henderson-Hasselbalch equation:

$$pH = pK + \log([base]/[acid])$$

BUFFERS

The ability of a weak acid and its corresponding anion (base) to resist change in the pH of a solution on the addition of a strong acid or base is referred to as *buffering*. An acid–base pair is most efficient in functioning as a buffer at a pH close to its p*K*. The principal extracellular buffer is the carbonic acid/bicarbonate (H_2CO_3/HCO_3^-) system. Other physiologic buffers include plasma proteins, hemoglobin, and phosphates. Because the isohydric principle requires that all buffer systems remain in chemical equilibrium, the complex buffering of biologic fluids can be analyzed based on a single buffer pair.

The carbonic acid/bicarbonate buffer system plays a unique role in acid–base homeostasis. In addition to being the most abundant extracellular buffer, the components of this buffer pair are under dynamic regulation by the body. In the presence of carbonic anhydrase, carbonic acid, $[H_2CO_3]$ is in equilibrium with carbon dioxide (CO_2) gas. Changes in ventilation that alter the partial pressure of CO_2 (Pco_2) in the blood regulates the carbonic acid level in the blood. The bicarbonate concentration is independently regulated by the kidney. Because the p*K* for the carbonic acid/bicarbonate system is 6.1, the relationship between pH, carbonic acid, and bicarbonate concentrations can be described by the Henderson-Hasselbalch equation. The concentration of carbonic acid is directly proportional to the amount of CO_2 dissolved in blood, which is equal to the product of Pco_2 and its solubility in physiologic fluids, ($Pco_2 \times 0.03$ for Pco_2 expressed in mm Hg [or $Pco_2 \times 0.226$ for Pco_2 expressed in kPa). This term can therefore be substituted into the equation below in place of $[H_2CO_3]$.

$$pH = 6.1 + ([HCO_3^-]/[H_2CO_3])$$
$$pH = 6.1 + \log([HCO_3^-]/(Pco_2 \times 0.03)) \text{ for } Pco_2 \text{ in mm Hg}$$

or

$$pH = 6.1 + \log([HCO_3^-]/(Pco_2 \times 0.226)) \text{ for } Pco_2 \text{ in kPa}$$

Thus, hydrogen ion concentration and pH are determined not by the absolute amounts of bicarbonate and Pco_2, but by their ratio.[1] Under normal physiologic conditions, the kidneys maintain the serum bicarbonate at approximately 24 mEq/L (24 mmol/L), whereas the lungs maintain the Pco_2 at approximately 40 mm Hg (5.3 kPa). The normal physiologic pH is thus 7.4:

$$pH = 6.1 + \log[24/(0.03 \times 40)] \text{ (or } pH = 6.1 + \log[24/(0.226 \times 5.3)])$$
$$pH = 6.1 + 1.3 = 7.4$$

If, in response to an acid load, the serum bicarbonate concentration were to decrease to 12 mEq/L (12 mmol/L), the predicted pH would be:

$$[HCO_3^-] = 12 \text{ mEq/L (12 mmol/L)}$$
$$Pco_2 = 40 \text{ mm Hg(5.3 kPa)}$$
$$pH = 6.1 + \log[12/(0.03 \times 40)] \text{ or}$$
$$pH = 6.1 + \log[12/(0.226 \times 5.\ 3)]$$
$$pH = 6.1 + 1.0 = 7.1$$

However, the normal respiratory response to an acid load is hyper-ventilation. As a result, if the Pco_2 decreased to approximately 26 mm Hg, the change in pH would be less:

$$[HCO_3^-] = 12 \text{ mEq/L (12 mmol/L)}$$
$$Pco_2 = 26 \text{ mm Hg(3.5 kPa)}$$
$$pH = 6.1 + \log[12/(0.03 \times 26)]$$
$$\text{(or } pH = 6.1 + \log[12/(0.226 \times 3.5)])$$
$$pH = 6.1 + 1.19 = 7.29$$

Thus, the physiologic regulation of both Pco_2 and $[HCO_3^-]$ permit the carbonic acid/bicarbonate system to provide more effective buffering of the extracellular fluids than could be achieved on the basis of chemical buffering alone.

REGULATION OF ACID–BASE HOMEOSTASIS

Cellular metabolism results in the production of large quantities of hydrogen that need to be excreted to maintain acid–base balance. In addition, small amounts of acid and alkali are also presented to the body through the diet. The bulk of acid production is in the form of CO_2, with the average adult producing approximately 15,000 mmol of CO_2 each day from the catabolism of carbohydrate, protein, and fat.[2] When respiratory function is normal, the amount of CO_2 produced metabolically is equal to the amount lost by respiration, and the blood CO_2 concentration remains constant.

Digestion of dietary substances and tissue metabolism also results in the production of nonvolatile acids. These acids are derived primarily from the sulfur-containing amino acids cysteine and methionine, as well as from ingested sulfur. In addition, phosphates are generated from the metabolism of proteins and phospholipids.

Neutral substances such as glucose can also be incompletely metabolized to intermediates, such as lactic and pyruvic acid, and fatty acids can be incompletely metabolized to acetoacetic acid and β-hydroxybutyric acid. These dietary and metabolic fixed acids are excreted, primarily by the kidney, to maintain acid–base homeostasis. On average, daily fixed acid excretion is approximately 0.8 mEq/kg per day (0.8 mmol/kg per day).[3]

Three mechanisms, each of which vary in their onset, collectively maintain acid–base balance: extracellular buffering, ventilatory regulation of carbon dioxide elimination, and renal regulation of hydrogen ion and bicarbonate excretion. Extracellular buffering occurs rapidly and is the body's first defense against a sudden increase in hydrogen ion concentration. Hyperventilation will then result in a decrease in P_{CO_2}, returning blood pH toward normal. Finally, the kidney will excrete the excess hydrogen ion, with the resultant return of acid–base balance to normal over a period of day(s).

EXTRACELLULAR BUFFERING

The body's buffering system can be divided into three components: bicarbonate/carbonic acid, proteins, and phosphates. The bicarbonate buffer is the most important of the body's buffers, because (1) there is more bicarbonate present in the extracellular fluid (ECF) than any other buffer component; (2) the supply of carbon dioxide is unlimited; and (3) the acidity of ECF can be regulated by controlling either the bicarbonate concentration or the P_{CO_2}.

Carbonic acid represents the respiratory component of the buffer pair because its concentration is directly proportional to the P_{CO_2}, which is determined by ventilation. Bicarbonate represents the metabolic component because the kidney may alter its concentration by reabsorption, generating new bicarbonate, or altering elimination.[4] The bicarbonate buffer system easily adapts to changes in acid–base status by alterations in ventilatory elimination of acid (P_{CO_2}) and/or renal elimination of base (HCO_3^-).

The phosphate buffer system consists of serum inorganic phosphate (3.5 to 5 mg/dL [1.13–1.62 mmol/L]), intracellular organic phosphate, and calcium phosphate in bone. Extracellular phosphate is present only in low concentrations, so its usefulness as a buffer is limited; however, as an intracellular buffer, phosphate is more useful. Calcium phosphate in bone is relatively inaccessible as a buffer, but prolonged metabolic acidosis will result in the release of phosphate from bone.

Intracellular and extracellular proteins also act as buffering systems. The charged side chains of amino acids provide the buffering action. Because the concentration of protein is much greater intracellularly than extracellularly, protein is much more important as an intracellular buffer.

RESPIRATORY REGULATION

The second mechanism for maintenance of acid–base homeostasis is control of ventilation. Both the rate and depth of ventilation can be varied to allow for excretion of CO_2 generated by diet and tissue metabolism. Medullary chemoreceptors in the brainstem sense changes in P_{CO_2} and in pH and modulate the control of breathing. Increasing minute ventilation (the total amount of air exhaled over a 1-minute period), by increasing respiratory rate and/or tidal volume (the amount of air exhaled in one breath), will increase CO_2 excretion and decrease the blood P_{CO_2}. Conversely, decreasing minute ventilation decreases CO_2 excretion and increases blood P_{CO_2}. This system rapidly adjusts within minutes to changes in acid–base balance.[2]

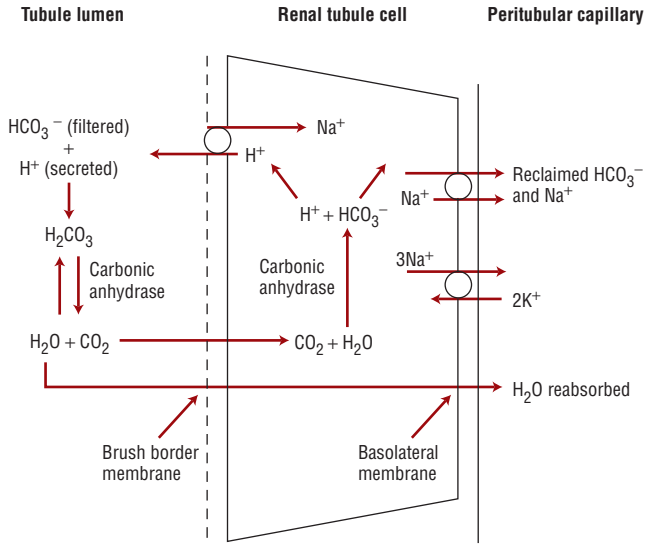

FIGURE 61-1. Proximal tubular bicarbonate reabsorption. In the tubular lumen, filtered bicarbonate (HCO_3^-) combines with hydrogen ion (H^+) secreted by an apical sodium ion (Na^+)-H^+ exchanger to form carbonic acid (H_2CO_3). The carbonic acid is rapidly broken down to carbon dioxide (CO_2) and water by carbonic anhydrase located on the luminal surface of the brush border membrane. The CO_2 then diffuses into the proximal tubular cell, where it reforms carbonic acid in the presence of intracellular carbonic anhydrase. The carbonic acid dissociates the former hydrogen ion that can again be secreted into the tubular lumen, and bicarbonate that exits the cell across the basolateral membrane and enters the peritubular capillary.

RENAL REGULATION

1 Because bicarbonate is a small ion, it is freely filtered at the glomerulus. The bicarbonate load delivered to the nephron is approximately 4,500 mEq/day (4,500 mmol/day). To maintain acid–base balance, this entire filtered load must be reabsorbed. Bicarbonate reabsorption occurs primarily in the proximal tubule (Fig. 61–1). In the tubular lumen, filtered bicarbonate combines with hydrogen ion secreted by the apical sodium ion (Na^+)-H^+-exchanger to form carbonic acid. The carbonic acid is rapidly broken down to CO_2 and water by carbonic anhydrase located on the luminal surface of the brush border membrane. The CO_2 then diffuses into the proximal tubular cell, where it reforms carbonic acid in the presence of intracellular carbonic anhydrase. The carbonic acid dissociates to form hydrogen ion, that can again be secreted into the tubular lumen, and bicarbonate that exits the cell across the basolateral membrane and enters the peritubular capillary.

Excretion of metabolic fixed acids and generation of new HCO_3^- is achieved through renal ammoniagenesis and distal tubular hydrogen ion secretion. Ammoniagenesis plays a critical role in acid–base homeostasis, with ammonium (NH_4^+) excretion comprising approximately 50% of renal net acid excretion. Ammonium is generated from the deamination of glutamine in the proximal tubule. For each ammonium ion excreted in the urine, one bicarbonate ion is regenerated and returned to the circulation.[5]

Distal tubular hydrogen ion secretion accounts for the remaining 50% of net acid excretion (Fig. 61–2). In the distal tubular cell, CO_2 combines with water in the presence of intracellular carbonic anhydrase to form carbonic acid, which dissociates to H^+ and HCO_3^-. The H^+ is actively transported into the tubular lumen by a H^+-adenosine triphosphatase (ATPase). The

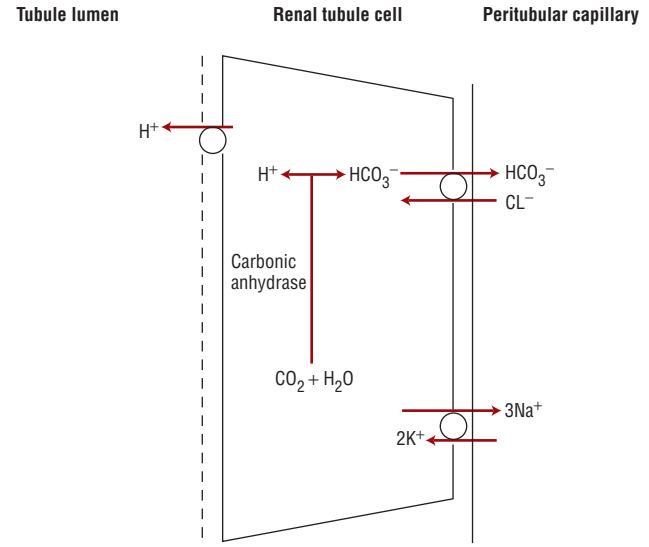

FIGURE 61-2. Collecting duct acid excretion. Hydrogen ion (H^+) and bicarbonate (HCO_3^-) are generated intracellularly from carbon dioxide (CO_2) and water, in the presence of intracellular carbonic anhydrase. The hydrogen ion is actively secreted into the tubular lumen by H^+-adenosine triphosphatase (ATPase) located in the apical (luminal) membrane. Bicarbonate exits the cell across the basolateral membrane and enters the peritubular capillary. (Cl^-, chloride ion; Na^+, sodium ion.)

bicarbonate exits the cell across the basolateral membrane and enters the circulation.[5]

ACID–BASE DISTURBANCES

2 Alterations in blood pH are designated by the suffix "-emia"; *acidemia* is an arterial blood pH <7.35 and *alkalemia* is an arterial blood pH >7.45. The pathophysiologic processes that result in alterations in blood pH are designated by the suffix "-osis." These disturbances are classified as either metabolic or respiratory in origin. In metabolic acid–base disorders, the primary disturbance is in the plasma bicarbonate concentration. Metabolic acidosis is characterized by a decrease in the plasma bicarbonate concentration whereas in metabolic alkalosis the plasma bicarbonate concentration is increased. Respiratory acid–base disorders are caused by alterations in alveolar ventilation that produce corresponding changes in the partial pressure of carbon dioxide from arterial blood ($Paco_2$). In respiratory acidosis, the $Paco_2$ is elevated; in respiratory alkalosis, it is decreased. Each disturbance has a compensatory (secondary) response that attempts to correct the HCO_3^-: $Paco_2$ ratio toward normal and mitigate the change in pH (Table 61–2). Although the time course of the respiratory compensatory responses to metabolic disturbances is rapid, the metabolic compensation for respiratory disturbances is slow. As a result, respiratory disturbances are characterized as acute (minutes to hours in duration), indicating that there has not been sufficient time for metabolic compensation, or chronic (days), indicating sufficient time for metabolic compensation has elapsed.

TABLE 61-2 Interpretation of Simple Acid–Base Disorders

Acid–Base Disorder	pH	Primary Disturbances	Compensation
Acidosis			
Respiratory	Decrease	Increase $Paco_2$	Increase HCO_3^-
Metabolic	Decrease	Decrease HCO_3^-	Decrease $Paco_2$
Alkalosis			
Respiratory	Increase	Decrease $Paco_2$	Decrease HCO_3^-
Metabolic	Increase	Increase HCO_3^-	Increase $Paco_2$

HCO_3^-, bicarbonate; $Paco_2$, partial pressure of carbon dioxide from arterial blood.

TABLE 61-3 Normal Blood Gas Values

	Arterial Blood	Mixed Venous Blood
pH	7.40 (7.35–7.45)	7.38 (7.33–7.43)
Po_2	80–100 mm Hg (10.6–13.3 kPa)	35–40 mm Hg (4.7–5.3 kPa)
Sao_2	95%	70%–75%
Pco_2	35–45 mm Hg (4.7–6.0 kPa)	45–51 mm Hg (4.7–6.8 kPa)
HCO_3^-	22–26 mEq/L (22–26 mmol/L)	24–28 mEq/L (24–28 mmol/L)

HCO_3^-, bicarbonate; Pco_2, partial pressure of carbon dioxide; Po_2, partial pressure of oxygen; Sao_2, saturation of arterial oxygen.

CLINICAL ASSESSMENT OF ACID–BASE STATUS

3 Blood gases are measured to determine the patient's oxygenation and acid–base status. Under normal circumstances, there is no clinically significant difference in pH between arterial and mixed venous blood. Arterial samples are designated with the letter "a" (e.g., partial pressure of oxygen from arterial blood [Pao_2] and $Paco_2$), whereas mixed venous samples are labeled with the letter "v" or not labeled (e.g., partial pressure of oxygen from venous blood [Pvo_2] and partial pressure of carbon dioxide from venous blood [$Pvco_2$]). The normal values for arterial and venous blood gases are shown in Table 61–3. Arterial blood reflects how well the blood is being oxygenated by the lungs (an accurate measurement of Pao_2), whereas venous blood reflects how much oxygen tissues are using. Arterial blood rather than venous blood should be used whenever possible because venous blood obtained from an extremity can provide misleading information. If metabolism in the extremity is altered by hypoperfusion, exercise, infection, or some other cause, the difference in the amount of dissolved oxygen between arterial and venous blood can be dramatic. The venous pH and Pco_2 during cardiopulmonary resuscitation, might be significantly lower and higher, respectively, than the arterial pH and arterial Pco_2. This indicates a severe tissue acidosis from CO_2 accumulation caused by hypoperfusion.

ANALYSIS OF ARTERIAL BLOOD GAS DATA

Arterial blood gases provide an assessment of the patient's acid–base status.[6] Low pH values (<7.35) indicate an acidemia, whereas high pH values (>7.45) indicate an alkalemia (Fig. 61–3). In a metabolic acidosis, the pH is decreased in association with a decreased serum bicarbonate concentration and a compensatory decrease in $Paco_2$. In a respiratory acidosis, the pH is decreased; the $Paco_2$, however, is elevated. The serum bicarbonate concentration is variable, depending on whether it is an acute disturbance (minimal increase in serum bicarbonate) or a chronic respiratory acidosis (substantial increase in serum bicarbonate). In a metabolic alkalosis, the pH is elevated in association with an increased bicarbonate concentration and a compensatory increase in $Paco_2$. In respiratory alkalosis, the pH is also elevated; the $Paco_2$, however, is decreased. As with respiratory acidosis, the metabolic compensation is variable, with a minimal decrease in serum bicarbonate in acute respiratory alkalosis and a larger decrease in [HCO_3^-] in chronic respiratory alkalosis. Although

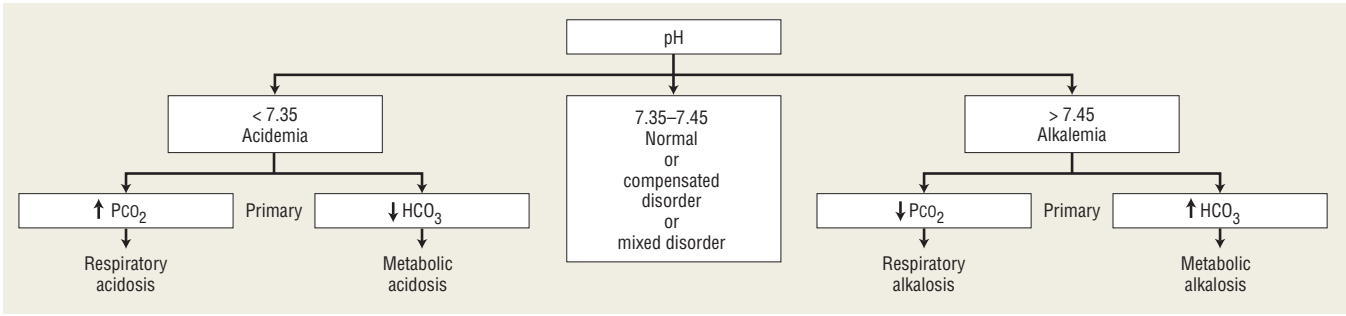

FIGURE 61-3. Analysis of arterial blood gases. (HCO_3^-, bicarbonate; P_{CO_2}, partial pressure of carbon dioxide.)

each measurement has a normal range (see Table 61–3), it is often easiest to consider the midpoint of each range as the normal value. This would correlate to a pH of 7.4, $Paco_2$ of 40 mm Hg (5.3 kPa) and HCO_3^- of 24 mEq/L (24 mmol/L). Steps in acid–base interpretation are described in Table 61–4.

When arterial blood gases differ significantly from those expected on the basis of the patient's clinical condition and previous laboratory determinations, additional venous blood samples should be drawn to assess plasma electrolyte concentrations. The bicarbonate calculated from the patient's $Paco_2$ and pH of the blood gas should be compared with the measured total CO_2 content (the amount of CO_2 gas extractable from plasma, consisting of HCO_3^-, H_2CO_3, and Pco_2). Ordinarily, the blood gas bicarbonate value is approximately 1 to 2 mEq/L (1–2 mmol/L) less than total CO_2 content.[3] If these values do not correspond, the results should be interpreted with caution because the difference can reflect an error in the blood collection or storage of the sample, or in the calibration of the blood gas analyzer.

METABOLIC ACID–BASE DISORDERS

METABOLIC ACIDOSIS

Pathophysiology

Metabolic acidosis is characterized by a decrease in pH as the result of a primary decrease in serum bicarbonate concentration. This can result from the buffering (consumption of HCO_3^-) of an exogenous acid, an organic acid accumulating because of a metabolic disturbance (e.g., lactic acid or ketoacids), or the progressive accumulation of endogenous acids secondary to impaired renal function (e.g., phosphates and sulfates).[7] The serum HCO_3^- can also be decreased as the result of a loss of bicarbonate-rich body fluids (e.g., diarrhea, biliary drainage, or pancreatic fistula) or occur secondary to the rapid administration of non-alkali–containing intravenous fluids (dilutional acidosis).[8]

TABLE 61-4 Steps in Acid–Base Diagnosis

1. Obtain arterial blood gases (ABGs) and electrolytes simultaneously.
2. Compare [HCO_3^-] on ABG and electrolytes to verify accuracy.
3. Calculate anion gap (AG).
4. Is acidemia (pH <7.35) or alkalemia (pH >7.45) present?
5. Is the primary abnormality respiratory (alteration in $Paco_2$) or metabolic (alteration in HCO_3)?
6. Estimate compensatory response (Table 60–7).
7. Compare change in [Cl^-] with change in [Na^+].

[Cl^-], chloride ion; [HCO_3^-], bicarbonate; [Na^+], sodium ion; $Paco_2$, partial pressure of carbon dioxide from arterial blood.

The serum anion gap (SAG), as defined below, can be used to infer whether an organic or mineral acidosis is present.

$$SAG = [Na^+] - [Cl^-] - [HCO_3^-]$$

To maintain electroneutrality, the total concentration of cations in the serum must equal the total concentration of anions.

$$[Na^+] + [UCs] = ([Cl^-] + [HCO_3^-]) + [UAs]$$

The cation concentration is equal to the sodium concentration plus that of "unmeasured" cations (UCs), predominantly magnesium, calcium, and potassium. The anion concentration is equal to the concentrations of chloride, bicarbonate, and "unmeasured" anions (UAs), including proteins, sulfates, phosphates, and organic anions. Therefore, as the result of the combination of the two equations above, the SAG can be expressed as:

$$SAG = [UAs] - [UCs]$$

The normal SAG is approximately 9 mEq/L (9 mmol/L), with a range of 3 to 11 mEq/L (3–11 mmol/L). This value is lower than the value of 12 mEq/L (12 mmol/L) cited in the literature in the past because of changes in the instrumentation for measurement of serum electrolytes.[7] Increases in the anion gap to values in excess of 17 to 20 mEq/L (17–20 mmol/L) are indicative of the accumulation of unmeasured anions in ECF.

These unmeasured anions are generated as the result of the consumption of HCO_3^- by endogenous organic acids such as lactic acid, acetoacetic acid, or β-hydroxybutyric acid or from the ingestion of toxins such as methanol or ethylene glycol. The degree of elevation in the SAG is dependent on the clearance of the anion, as well as the multiple factors that influence HCO_3^- concentrations. Thus the SAG is a relative rather than an absolute indication of the cause of metabolic acidosis. The SAG can also be elevated in the metabolic acidosis because of renal failure, as the result of the accumulation of various organic anions, phosphates, and sulfates.

In hyperchloremic metabolic acidosis, bicarbonate losses from the ECF are replaced by chloride, and the SAG remains normal. This decrease in bicarbonate may be due to gastrointestinal tract losses, dilution of bicarbonate in the ECF as the result of the addition of sodium chloride solutions or chloride-containing acids. Common causes of metabolic acidosis with an increased or a normal SAG are listed in Table 61–5.

Hyperchloremic Metabolic Acidosis

Hyperchloremic metabolic acidosis can result from increased gastrointestinal bicarbonate loss, renal bicarbonate wasting, impaired renal acid excretion, or exogenous acid gain. Gastrointestinal

TABLE 61-5 Common Causes of Metabolic Acidosis

Increased Serum Anion Gap	Normal Serum Anion Gap/ Hyperchloremic States
Lactic acidosis	**Gastrointestinal bicarbonate loss**
Diabetic ketoacidosis	Diarrhea
Lactic acidosis (see Table 61–6)	External pancreatic or small bowel drainage (fistula)
Renal failure (acute or chronic)	Ureterosigmoidostomy, ileostomy
Methanol ingestion	**Drugs**
Ethylene glycol ingestion	Calcium chloride (acidifying agent)
Salicylate overdosage	Magnesium sulfate (diarrhea)
Starvation	Calcium chloride (acidifying agent)
	Renal tubular acidosis
	Hypokalemia
	Proximal renal tubular acidosis (type II)
	Distal renal tubular acidosis (type I)
	Carbonic anhydrase inhibitors (e.g., acetazolamide)
	Hypokalemia
	Generalized distal nephron dysfunction (type IV)
	Mineralocorticoid deficiency or resistance
	Tubulointerstitial disease
	Drug-induced hyperkalemia
	Potassium-sparing diuretics (amiloride, spironolactone, triamterene)
	Trimethoprim
	Pentamidine
	Heparin
	Angiotensin-converting enzyme inhibitors and receptor blockers
	Nonsteroidal anti-inflammatory drugs
	Cyclosporin A
	Other
	Acid ingestion (ammonium chloride, hydrochloric acid, hyperalimentation)
	Expansion acidosis (rapid saline administration)

disorders such as diarrhea, biliary or pancreatic drainage through either a surgical drain or fistula can result in the loss of large volumes of bicarbonate-containing fluids. Severe diarrhea, the most common cause of hypochloremic metabolic acidosis, can lead to a daily loss of 5 to 10 L of fluid containing 100 to 140 mEq/L (100–140 mmol/L) of sodium, 20 to 40 mEq/L (20–40 mmol/L) of potassium, 80 to 100 mEq/L (80–100 mmol/L) of chloride, and 30 to 50 mEq/L (30–50 mmol/L) of bicarbonate.[4] Patients who have undergone ureteral diversion into the sigmoid colon or isolated ileal loop can also develop a hyperchloremic metabolic acidosis. This is the result of a net loss of bicarbonate given that chloride is reabsorbed and bicarbonate is secreted by gastrointestinal epithelial cells in the presence of the urine that is retained in the colon or bowel loop.

Hyperchloremic metabolic acidosis caused by renal bicarbonate wasting is the defining disturbance in proximal renal tubular acidosis and is a complication of therapy with carbonic anhydrase inhibitors. During the treatment of diabetic ketoacidosis, renal loss of β-hydroxybutyrate and acetoacetate, which would otherwise be metabolized to yield bicarbonate, can contribute to the development of hyperchloremic metabolic acidosis. Impaired renal acid excretion that occurs as a result of distal tubular dysfunction in patients with distal renal tubular acidoses can also occur in patients with moderate to severe renal insufficiency from other causes. The metabolic acidosis of renal insufficiency is initially hyperchloremic but can progress to an anion-gap acidosis as the renal insufficiency worsens and sulfates, phosphates, and other anions accumulate. Hyperchloremic metabolic acidosis can also result from the exogenous administration of acid (hydrochloric acid, ammonium chloride) or the unbuffered administration of acid salts from the amino acids in total parenteral nutrition fluids.

Renal Tubular Acidosis

4 Renal tubular disorders can involve the proximal tubule, with a resultant failure to reabsorb filtered bicarbonate, or affect acid excretion in the distal tubule. The distal renal tubular acidoses (RTAs) are the most common, and are all characterized by impaired net acid excretion. The distal RTAs are subdivided into those that are associated with hypokalemia (type I) and those associated with hyperkalemia (type IV). Patients with classic distal (type I) RTA have impaired hydrogen ion secretion and are unable to excrete the daily acid load necessary to maintain acid–base balance.[4] These patients are unable to maximally acidify their urine (i.e., attain urine pH <5.5), even in the face of an acid challenge. Type I RTA may be the result of a primary tubular defect or develop secondary to a wide variety of disorders including hypercalcemia, multiple myeloma, systemic lupus erythematosus, Sjögren syndrome, sickle-cell disease, and renal transplant rejection, or following the administration of amphotericin B or ingestion of toluene. The primary form of this disorder usually occurs in children and can result in severe acidosis, slowed growth, nephrocalcinosis, and kidney stones.[7,9] In adults, clinical complications include osteomalacia, nephrocalcinosis, and recurrent kidney stones. The hypokalemia associated with classic distal (type I) RTA results from secondary hypoaldosteronism associated with volume depletion. The renal potassium wasting decreases considerably if bicarbonate therapy is administered.

The hyperkalemic distal (type IV) RTAs are a heterogeneous group of disorders characterized by hypoaldosteronism or generalized distal tubule defects. The most common form of type IV RTA is hyporeninemic hypoaldosteronism. This syndrome is most commonly associated with mild renal insufficiency caused by diabetic nephropathy, but can also be seen in a variety of other disorders, including chronic interstitial nephritis, sickle-cell disease, human immunodeficiency virus (HIV) nephropathy, and obstructive uropathy. The clinical presentation of this syndrome is often exacerbated by pharmacologic therapy with agents that can interfere with the renin-angiotensin-aldosterone axis, such as β-adrenergic blockers, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, and nonsteroidal antiinflammatory drugs. Heparin can induce the syndrome by inhibiting adrenal aldosterone biosynthesis. Patients with this form of RTA are able to maximally acidify their urine (urine pH <5.5).[9] The primary defect in acid excretion is impaired ammoniagenesis caused by mild renal insufficiency. Hyperaldosteronism predisposes to the development of hyperkalemia, which results in further impairment of ammoniagenesis. Treatment to control the hyperkalemia is usually sufficient to reverse the metabolic acidosis, and mineralocorticoid replacement is frequently unnecessary.

Hyperkalemic distal (type IV) RTA resulting from generalized distal tubule defects is less common than hyporeninemic hypoaldosteronism but is more common than classic distal (type I) RTA. Patients with this defect have impaired tubular potassium secretion in addition to impaired urinary acidification (urine pH >5.5, despite acidemia or acid loading). Urinary obstruction is the most frequent cause of this disorder, which can also be associated with sickle-cell nephropathy, systemic lupus erythematosus, HIV nephropathy, analgesic abuse nephropathy, amyloidosis, renal transplant rejection, and chronic cyclosporine nephrotoxicity.

Proximal (type II) RTA is characterized by defects in proximal tubular reabsorption of bicarbonate. Normally, more than 85% of filtered bicarbonate is reabsorbed in the proximal tubule. Defects in proximal tubular bicarbonate reabsorption result in increased delivery of bicarbonate to the distal nephron, which has a limited capacity for bicarbonate reabsorption. As a result, at a normal serum bicarbonate concentration, the filtered bicarbonate load is

incompletely reabsorbed, and is lost in the urine. As the serum bicarbonate concentration decreases, the filtered load of bicarbonate is proportionately decreased. A new equilibrium is established in which the kidney is able to reabsorb the filtered bicarbonate load, albeit at a reduced serum bicarbonate concentration. Thus patients with proximal RTA present with a chronic, nonprogressive hyperchloremic metabolic acidosis. These patients are able to acidify their urine in response to an acid load, but develop bicarbonaturia at a reduced serum bicarbonate concentration following bicarbonate loading. The impaired bicarbonate reabsorption results in salt wasting and secondary hyperaldosteronism. Hypokalemia, which can be severe, usually develops as a result of the hyperaldosteronism and bicarbonaturia.[4,7] Unlike patients with classic distal (type I) RTA, the hyperkalemia if present in proximal RTA is exacerbated by alkali replacement. Proximal RTA can develop as an isolated defect, or it can be associated with generalized proximal tubular dysfunction (Fanconi syndrome), with impaired proximal tubular glucose, phosphate, and amino acid reabsorption. Proximal RTA usually presents as an acquired disorder, secondary to a variety of diseases (amyloidosis, multiple myeloma, or nephrotic syndrome) or exposure to toxins (lead, cadmium, mercury, or outdated tetracyclines). Pharmacologic therapy with carbonic anhydrase inhibitors produces an iatrogenic form of proximal RTA.

TABLE 61-6 Causes of Lactic Acidosis

Primary decrease in tissue oxygenation
Shock
Severe anemia
Congestive heart failure
Asphyxia
Carbon monoxide poisoning
Deranged oxidative metabolism
Medications
Catecholamines
Linezolid
Metformin
Nalidixic acid
Nucleoside-analog reverse transcriptase inhibitors (didanosine, stavudine, zidovudine)
Overdose (iron, isoniazid, salicylates, theophylline)
Propofol infusion syndrome
Propylene glycol toxicity (IV lorazepam)
Sodium nitroprusside (secondary to cyanide toxicity)
Streptozocin
Diabetes mellitus
Malignancy
Seizures
Methanol, ethanol, or ethylene glycol
Disorders associated with inborn errors of metabolism

Elevated Anion Gap Metabolic Acidosis

Metabolic acidosis with an increased SAG commonly results from increased endogenous organic acid production. In lactic acidosis, lactic acid accumulates as a by-product of anaerobic metabolism. Accumulation of the ketoacids β-hydroxybutyric acid and acetoacetic acid defines the ketoacidosis of uncontrolled diabetes mellitus, alcohol intoxication, and starvation (see Table 61–5). In advanced renal failure, accumulation of phosphate, sulfate, and organic anions is responsible for the increased SAG, which is usually less than 24 mEq/L (24 mmol/L).[10] The severe metabolic acidosis seen in myoglobinuric acute renal failure caused by rhabdomyolysis may be caused by the metabolism of large amounts of sulfur-containing amino acids released from myoglobin.

The presence of mild elevations in the SAG cannot be automatically attributed to the presence of a high SAG metabolic acidosis. Elevations in the SAG are commonly seen in hospitalized patients, especially those who are critically ill.[10] A variety of factors can contribute to this nonspecific elevation in the SAG, including the presence of alkalemia, which increases the anionic charge of albumin and other plasma proteins. The usefulness of the SAG as a marker of acid–base status is dependent on proper interpretation of a patient's clinical status.[5,11] Despite these limitations, when the SAG exceeds 20 to 25 mEq/L (20–25 mmol/L) a significant organic acidosis is likely to be present.

High anion gap metabolic acidosis can develop in many clinical settings, including uncontrolled diabetes mellitus (see Chapter 83), alcohol intoxication (see Chapters 44 and 75), and starvation (see Chapter 72). Toxic ingestions of methanol and ethylene glycol, are also associated with high anion gap metabolic acidosis and can be differentiated from other causes of SAG because of the presence of an elevated osmolar gap. The mechanisms responsible for the development of acidosis in these settings are diverse.[12] (See type I diabetes + ketoacidosis case in Casebook.)

Lactic Acidosis Lactic acidosis is one of the most common causes of high SAG metabolic acidosis and can impact approximately 1% of hospitalized patients. Lactic acid is the end product of anaerobic metabolism of glucose (glycolysis).[13] In normal individuals, lactic acid derived from pyruvate enters the circulation in small amounts and is promptly removed by the liver. In the liver, and to a lesser extent in the kidney, lactic acid is reoxidized to pyruvic acid, which is then metabolized to CO_2 and H_2O. The normal plasma lactate concentration in healthy subjects is approximately 1 mEq/L (1 mmol/L).[3,12,13] The diagnosis of lactic acidosis should be considered in all patients with metabolic acidosis associated with an increased SAG. Lactic acidosis is considered to be present when lactate concentrations exceed 4 to 5 mEq/L (4–5 mmol/L) in an acidemic patient.

Classically, lactic acidosis has been differentiated into disorders associated with tissue hypoxia (type A lactic acidosis) and disorders associated with deranged oxidative metabolism (type B lactic acidosis), although the distinction between them is blurred (Table 61–6). The etiologies of lactic acidosis can also be categorized on the basis of changes in lactate production and/or utilization.[12,13] Metabolic disturbances can result in increased tissue pyruvate production or impaired utilization, with proportional increases in lactate concentrations. Increased lactate production is more commonly associated with alterations in tissue redox state, resulting in preferential conversion of pyruvate to lactate. During anaerobic metabolism, reduced nicotinamide adenine dinucleotide accumulates, driving the conversion of pyruvate to lactate and increasing the lactate:pyruvate ratio. States of enhanced metabolic activity (e.g., grand mal seizures, strenuous exercise, or hyperthermia), decreased tissue oxygen delivery (e.g., severe anemia, hypoxia, circulatory shock, or carbon monoxide poisoning) or impaired oxygen utilization (e.g., cyanide toxicity) all are associated with lactic acidosis. Impaired hepatic clearance of lactate, as seen in hypoperfusion states, liver failure, and alcohol intoxication, can also result in lactic acidosis.

Cardiovascular and septic shock, with resultant tissue hypoperfusion, are the most common causes of lactic acidosis. Poor tissue perfusion and hypoxia influence enzymatic pyruvate and lactate metabolism to stimulate anaerobic glycolysis and to decrease lactate utilization. This leads to hyperlactatemia and lactic acidosis. The mortality rate of this type of lactic acidosis can be as high as 80% and correlates with the degree of hyperlactatemia.

Lactic acidosis associated with liver disease, toxins, and congenital enzyme deficiency can be caused by deranged oxidative metabolism or impaired lactate clearance.[4,13] The exact role of diabetes mellitus

in the induction of lactic acidosis is not clear. It may involve a decrease in pyruvate dehydrogenase activity, the enzyme responsible for pyruvate metabolism. Lactic acidosis in neoplastic disease is uncommon and reported mostly in patients with myeloproliferative disorders. Leukocytes and neoplastic cells in general have high rates of glycolysis. In the case of a large tumor or tightly packed bone marrow, oxygenation can be decreased, favoring the accumulation of lactate. Lactic acidosis has been reported in patients with massive liver tumors, and it has been postulated that the liver uptake of lactate is decreased in these patients. Lactic acidosis associated with seizures is usually transient and occurs because of excessive muscle activity.[13]

A number of medications can cause lactic acidosis.[13–23] Two of the most common medications associated with the development of lactic acidosis are nucleoside-analog reverse transcriptase inhibitors (NRTIs) (3.9 cases per 1,000 person-years) and metformin (0.03 cases per 1,000 person-years).[15–18] The proposed mechanism of NRTI-induced lactic acidosis is the inhibition of the enzyme DNA polymerase gamma that is responsible for mitochondrial DNA synthesis.[15] Disruption of this enzyme can inhibit the transport of lactate into the mitochondria, leading to an accumulation in the cytoplasm. Stavudine is the NRTI most frequently associated with lactic acidosis; however, the combination of stavudine and didanosine confers the highest risk.

The primary suspected mechanism for metformin-induced lactic acidosis is inhibition of liver gluconeogenesis as the result of its inhibitory effects on pyruvate carboxylase which is necessary for the conversion of pyruvate to glucose.[16,17] Other possible pathways for metformin-associated lactic acidosis include a decrease in both hepatic intracellular pH and cardiac output and an increase in lactate production in the gut and increased renal loss of bicarbonate.[14] Risk factors for metformin-induced lactic acidosis include renal insufficiency, liver disease, dehydration, advanced age, alcohol consumption, and supratherapeutic dosing. Metformin should be discontinued during periods of tissue hypoxia (e.g., myocardial infarction, sepsis), for 3 days after contrast media has been administered or 2 days before general anesthesia administration. In the latter two cases, metformin should only be reinstituted when the patient's renal function is stable.

Propylene glycol is commonly used as a solubilizing agent in intravenous drug preparations (e.g., lorazepam, pentobarbital) and is predominantly metabolized to lactic acid via the hepatic enzyme alcohol dehydrogenase. The administration of large doses of propylene glycol, particularly to patients with renal or liver insufficiency, can lead to a lactic acidosis with an osmolar gap and thus serial measurement of the osmolar gap can be used to detect propylene glycol accumulation.[18,19]

Reports of the association between propofol and lactic acidosis were initially described in children.[20] This association is now recognized in adults and has come to be known as the propofol-related infusion syndrome. In addition to lactic acidosis, cardiac failure, rhabdomyolysis, and renal failure have been observed primarily because of uncoupling of oxidative phosphorylation and impaired oxidation of free fatty acids. This syndrome is most frequently seen in patients receiving propofol at high doses (>5 mg/kg/h) for more than 2 days.

CLINICAL CONTROVERSY

The incidence of the propofol infusion syndrome among critically ill patients administered propofol is unknown and the role that worsening critical illness plays in patients with suspected propofol infusion remains unclear.

CLINICAL PRESENTATION

Chronic metabolic acidosis is usually not associated with severe acidemia and is relatively asymptomatic. The major manifestations are in the bones, where chronic acidemia causes bone demineralization with the development of rickets in children and osteomalacia and osteopenia in adults. In infants and children, chronic metabolic acidosis is associated with growth failure and short stature and can be associated with nonspecific symptoms including anorexia, nausea, weight loss, and muscle weakness.

Severe metabolic acidosis is usually associated with acute processes. The manifestations of severe acidemia (pH <7.20) involve the cardiovascular, respiratory, and central nervous systems. Hyperventilation is often the first sign of metabolic acidosis. At a pH of 7.2, pulmonary ventilation increases approximately fourfold, and an eightfold increase has been noted at a pH of 7.[24,25] Respiratory compensation can occur as Kussmaul respirations—the deep, rapid respirations seen commonly in patients with diabetic ketoacidosis. In extremely severe acidosis (pH <6.8), CNS function is disrupted to such a degree that the respiratory center is depressed.

CNS depression correlates more closely with spinal fluid pH than with blood pH. For this reason, neurologic symptoms tend to occur more frequently and to a greater degree in patients with respiratory acidosis because the CO_2 accumulated in the respiratory form readily crosses the blood-brain barrier to cause acidosis in the CNS.[1] Because of the slow penetration of administered bicarbonate into the CNS, the CNS pH fails to normalize as rapidly as blood pH. Therefore patients continue to hyperventilate because of sustained CNS acidity, and severe respiratory alkalosis can occur. Sustained lowering of the $Paco_2$ within 12 to 36 hours is to be anticipated during the correction of any metabolic acidosis.[1]

Systemic acidosis can cause peripheral arteriolar dilatation, characterized by flushing, a rapid heart rate, and wide pulse pressure. Initially, cardiac output can be increased, but as acidosis becomes more severe, myocardial contractility becomes impaired, and cardiac output decreases. The effects of vagal stimulation are also enhanced at pH levels lower than 7.1, probably as a consequence of inhibition of acetylcholinesterase. This increases the danger of vagally mediated bradycardia and heart block during acidosis.

Gastrointestinal symptoms of metabolic acidosis include loss of appetite, nausea, and vomiting. Severe acidosis (pH <7.1) interferes with carbohydrate metabolism and insulin utilization, and results in hyperglycemia. Metabolic acidosis alters potassium homeostasis and contributes to the development of hyperkalemia. The magnitude of the effect on serum potassium depends on the type of acidosis: Acidosis caused by mineral acids (e.g., hydrochloric acid) are associated with a greater change in potassium levels than acidosis caused by organic acids (e.g., lactic acidosis), in which the increase in potassium attributable to the acidosis per se is minimal.

CLINICAL PRESENTATION OF METABOLIC ACIDOSIS

General

- The patient is usually relatively asymptomatic if the acidosis is acute and mild. In those with severe acidemia (pH <7.15–7.20) the cardiovascular, respiratory, and central nervous systems can be affected.

Symptoms

- The patient may complain of loss of appetite, nausea, and vomiting.

Signs

- Cardiac: Flushing, a rapid heart rate, wide pulse pressure, and an increase in cardiac output can be seen initially. This can be

followed by a reduction in cardiac output, blood pressure, and liver and kidney blood flow.

- Cerebral: Obtundation or coma.
- Metabolic: Insulin resistance; increased protein degradation; increased metabolic demands.
- Gastrointestinal: Nausea, vomiting, loss of appetite.
- Respiratory: Dyspnea, hyperventilation with deep, rapid respirations is seen in those with severe acidosis.
- Chronic acidemia causes bone demineralization with the development of rickets in children and osteomalacia and osteopenia in adults.

Laboratory Tests

- Serum CO_2 is low. Hyperglycemia and hyperkalemia are common. Patients with a pH <7.2 are deemed to have a severe acidosis.

COMPENSATION

5 The patient's primary means to compensate for metabolic acidosis is to increase carbon dioxide excretion by increasing respiratory rate. This results in a decrease in $Paco_2$. This ventilatory compensation results from stimulation of the respiratory center by changes in cerebral bicarbonate concentration and pH.[1] For every 1-mEq/L (1 mmol/L) decrease in bicarbonate concentration below the average of 24, the $Paco_2$ decreases by approximately 1 to 1.5 mm Hg (0.13–0.20 kPa) from the normal value of 40 (5.3 kPa) (Table 61–7).

TABLE 61-7 Guidelines for Initial Interpretation of Acid–Base Disorders

Acidosis	
Metabolic	$Paco_2$ in mm Hg should decrease by 1.3 times the fall in plasma $[HCO_3^-]$ (in mEq/L) $Paco_2$ in kPa should decrease by 0.17 times the fall in plasma $[HCO_3^-]$ (in mmol/L)
Acute respiratory	The plasma $[HCO_3^-]$ should increase by 0.1 times the increase in $Paco_2$ ± 3 in mm Hg The plasma $[HCO_3^-]$ should increase by 0.75 times the increase in $Paco_2$ ± 0.4 in kPa
Chronic respiratory	The plasma $[HCO_3^-]$ should increase by 0.35 times the increase in $Paco_2$ ± 4 in mm Hg The plasma $[HCO_3^-]$ should increase by 2.6 times the increase in $Paco_2$ ± 0.5 in kPa
Alkalosis	
Metabolic	$Paco_2$ in mm Hg should increase by 0.4–0.6 times the rise in plasma $[HCO_3^-]$ (in mEq/L) $Paco_2$ in kPa should increase by 0.05–0.08 times the rise in plasma $[HCO_3^-]$ (mmol/L)
Acute respiratory	The plasma $[HCO_3^-]$ should decrease by 0.2 times the decrease in $Paco_2$ in mm Hg but usually not to <18 mEq/L The plasma $[HCO_3^-]$ should decrease by 1.5 times the decrease in $Paco_2$ in kPa but usually not to <18 mmol/L
Chronic respiratory	The plasma $[HCO_3^-]$ should fall by 0.35 times the decrease in $Paco_2$ in mm Hg but usually not to <14 mEq/L The plasma $[HCO_3^-]$ should fall by 2.6 times the decrease in $Paco_2$ in kPa but usually not to <14 mmol/L

HCO_3^-, bicarbonate; $Paco_2$, partial pressure of carbon dioxide from arterial blood.

Adapted from Kamel S, Razeen-Davids M, Lin, SH et al. Interpretation of electrolytes and acid-base parameters in blood and urine. In: Bremmer BM, ed. Bremmer and Rector's The Kidney, 8th ed. New York: Saunders, 2007:898–923. Copyright © Elsevier 2007.

The anticipated $Paco_2$ associated with a given bicarbonate concentration for patients with uncomplicated metabolic acidosis can be calculated as[25]:

$$Paco_2 = (1.5 \times [HCO_3^-]) + 8] \pm 2 \text{ for } Paco_2 \text{ in mm Hg}$$
$$(Paco_2 = (0.2 \times [HCO_3^-]) + 1.1] \pm 0.3 \text{ for } Paco_2 \text{ in kPa})$$

For example, 95% of patients with a plasma bicarbonate of 16 mEq/L (16 mmol/L) should have an arterial Pco_2 of 30 to 34 mm Hg (4.0–4.6 kPa). An observed arterial Pco_2 within this range is consistent with physiologic respiratory compensation for a metabolic acidosis and suggests that there is no respiratory disturbance. In contrast, if the Pco_2 is less than 30 mm Hg (4.0 kPa), a superimposed respiratory alkalosis can be present, whereas if the Pco_2 is greater than 34 mm Hg (4.6 kPa), a superimposed respiratory acidosis is likely present.

TREATMENT

Metabolic Acidosis

CHRONIC METABOLIC ACIDOSIS

6 Asymptomatic patients with mild to moderate degrees of acidemia (plasma bicarbonate of 12 to 20 mEq/L ([12–20 mmol/L]; pH 7.2–7.4) do not require emergent therapy. They can usually be managed with gradual correction of the acidemia, over a period of days to weeks, using oral sodium bicarbonate or other alkali preparations (Table 61–8). In all forms of chronic metabolic acidosis, primary therapy should be directed at treating the underlying disease state. Gastrointestinal pathology should be treated to reduce ongoing bicarbonate losses, and factors that exacerbate RTA should be treated. If acidemia persists, alkali therapy should be instituted with the goal of normalization of blood pH. The loading dose (LD) of alkali to initially correct the acidemia can be calculated as follows where V_D is the volume of distribution of bicarbonate[26]:

$$LD(\text{mEq or mmol/L}) = (V_D HCO_3^- \times \text{body weight [BW]}) \times (\text{desired } [HCO_3^-] - \text{current } [HCO_3^-])$$

For a 60-kg patient with a serum bicarbonate of 15 mEq/L (24–15 mmol/L), the loading dose is calculated thus:

$$LD(\text{mEq}) = (0.5 \text{ L/kg} \times 60 \text{ kg}) \times (24 \text{ mEq/L} - 15 \text{ mEq/L})$$
$$= 30 \text{ L} \times 9 \text{ mEq/L}$$
$$= 270 \text{ mEq/L(270 mmol/L)}$$

The calculated loading dose of alkali should be administered over several days to avoid volume overload from the accompanying sodium load. For this scenario, a regimen of 60 to 70 mEq (60–70 mmol) three times a day for 3 to 5 days should result in an increase in HCO_3^- levels toward normal. In addition to the calculated loading dose, supplemental alkali must also be provided to replace ongoing losses, which can be approximated to be 2 mEq/kg (2 mmol/kg) per day or 40 mEq (40 mmol) 3 times a day. In patients with associated volume depletion, bicarbonate replacement can be provided simultaneous with volume resuscitation by substituting bicarbonate for chloride in intravenous crystalloid solutions.

In patients with chronic metabolic acidosis because of gastrointestinal bicarbonate losses, maintenance therapy should provide sufficient alkali to replace ongoing bicarbonate losses. The magnitude of this replacement is variable and can be substantial (>10 mEq/kg [>10 mmol/kg] per day). In addition, associated losses of other electrolytes, such as potassium and magnesium, may need to be replaced (see Chapter 60).

TABLE 61-8 Therapeutic Alternatives for Oral Alkali Replacement

Generic Name	Trade Name(s)	Milliequivalents of Alkali	Dosage Form(s)	Comment
Shohl's solution Sodium citrate/citric acid	Bicitra (Willen)	1 mEq Na/mL; equivalent to 1 mEq bicarbonate	Solution (500 mg Na citrate, 334 mg citric acid/5 mL)	Citrate preparations increase absorption of aluminum
Sodium bicarbonate	Various (e.g., Sodamint)	3.9 mEq bicarbonate/tablet (325 mg)	325 mg tablet	Bicarbonate preparations can cause bloating because of CO_2 production
		7.8 mEq bicarbonate/tablet (650 mg)	650 mg tablet	
	Baking soda (various)	60 mEq bicarbonate/tsp (5 g/tsp)	Powder	
Potassium citrate	Urocit-K (Mission)	5 mEq citrate/tablet	5 mEq tablet	See above
Potassium bicarbonate/ potassium citrate	K-Lyte (Bristol)	25 mEq bicarbonate/tablet	25 mEq tablet (effervescent)	
	K-Lyte DS (Bristol)	50 mEq bicarbonate/tablet (double strength)	50 mEq tablet (effervescent)	See above
Potassium citrate/ citric acid	Polycitra-K (Willen)	2 mEq K/mL; equivalent to 2 mEq bicarbonate 30 mEq bicarbonate/ unit dose packet	Solution (1,100 mg K citrate, 334 mg citric acid/5 mL) Crystals for reconstitution (3,300 mg K citrate, 1,002 mg citric acid/unit dose packet)	See above
Sodium citrate/ potassium citrate/ citric acid	Polycitra (Willen) Polycitra-LC (Willen)	1 mEq K, 1 mEq Na/mL; equivalent to 2 mEq bicarbonate	Syrup (Polycitra) solution (Polycitra-LC) (Both contain 550 mg K citrate, 500 mg Na citrate, 334 mg citric acid/5 mL)	See above

Proximal (type II) RTA is a bicarbonate-wasting disorder that requires the administration of large maintenance doses of alkali (10–15 mEq/kg [10–15 mmol/kg] per day). As alkali replacement raises the serum bicarbonate concentration toward normal, the proximal tubule's capacity to reabsorb bicarbonate is overwhelmed, and renal bicarbonate wasting increases. In children, aggressive therapy of proximal RTA is necessary to avoid growth retardation and osteopenia. Because this is generally a mild, nonprogressive acidosis in adults, the benefit of alkali therapy is frequently outweighed by the risks of increased potassium wasting. In patients with classic distal (type I) RTA, maintenance therapy usually requires only enough alkali to buffer the amount of acid generated from dietary intake and metabolism. This usually approximates 1 to 3 mEq/kg per day (1–3 mmol/kg).

7 After initial potassium deficits are replaced, ongoing potassium supplementation may not be required, as renal potassium losses decrease following initiation of appropriate alkali therapy. The use of potassium alkali salts can, however, be desirable in patients with associated nephrolithiasis, because sodium salts can increase urinary calcium excretion.

The metabolic acidosis associated with hyperkalemic distal (type IV) RTA with hyporeninemic-hypoaldosteronemia that is often seen in patients with diabetes mellitus can be corrected by the treatment of hyperkalemia alone (see Chapter 60). The use of supplemental alkali (1–2 mEq/kg [1–2 mmol/kg] per day) to increase sodium intake and stimulate distal tubular potassium secretion can be beneficial. A minority of patients require the administration of pharmacologic amounts of fludrocortisone.[4] Type IV RTA resulting from a generalized distal tubular disorder often responds to low doses of alkali (1.5–2.0 mEq/kg [1.5–2.0 mmol/kg] per day).[27] Corrections of the acidosis along with modest dietary potassium restriction (to 1 mEq/kg [1 mmol/kg] per day) will often result in the maintenance of serum potassium levels of 5 mEq/L (5 mmol/L) or less.

ACUTE SEVERE METABOLIC ACIDOSIS

8 The management of patients with life-threatening acute metabolic acidosis (plasma bicarbonate of 8 mEq/L [8 mmol/L] and pH <7.20) is dependent on the underlying cause and the patient's cardiovascular status. In some cases patients will require emergent hemodialysis therapy (see Chapter 51). Patients with hyperchloremic acidosis (e.g., diarrhea-induced) are unable to regenerate bicarbonate, and the generation of new bicarbonate by the kidneys can require several days before one can observe a meaningful change in their status.[11] Thus intravenous alkali therapy is often required for these patients.

Although conventional wisdom recommends the use of alkali replacement in patients with severe acidemia because of the deleterious effects of acidemia on circulatory function,[6,10–12] studies have not demonstrated that its administration improves patient outcomes.[28–31] Alkali therapies may either improve or worsen clinically relevant endpoints such as $[H^+]$, $Paco_2$, lactate concentrations, and cardiac output. The specific patient populations most likely to benefit or be harmed from alkalinizing therapy are presented in Table 61–9.

There are several therapeutic alternatives available for the acute correction of severe metabolic acidosis. Sodium acetate, sodium citrate, and sodium lactate are unreliable sources of alkali because their alkalinizing effect is dependent on their oxidative conversion to bicarbonate. This process is often impaired in critically ill patients, especially those with liver disease or circulatory failure. Although sodium bicarbonate is the most widely used intravenous alkalotic agent,[11] several studies suggest that it is frequently ineffective and can actually be deleterious, especially in patients with lactic acidosis.[28–31] Two of the three remaining alternatives (Carbicarb and dichloroacetate) are investigational and not available in most clinical settings. Tromethamine, or THAM, is a carbon dioxide-consuming, commercially available solution that buffers respiratory as well as metabolic acids.

SODIUM BICARBONATE

While sodium bicarbonate administration provides fluid and electrolyte replacement and increases arterial pH, neither animal nor

TABLE 61-9 Patients Likely to Benefit or Be Harmed from Alkalinizing Therapy

Potential for Benefit	Potential for Harm
Distal (type 1) renal tubular acidosis	Hypernatremia
Severe hypchloremic metabolic acidosis secondary to diarrhea or surgical diversion	Hypernatremia
	Acute renal failure
	Congestive heart failure
Specific poisonings and intoxications (e.g., salicylate overdose with metabolic acidosis)	Pulmonary disease resulting in decreased ventilation
	Acute lung injury where lung-protective ventilation strategy is used
	Diabetic ketoacidosis

clinical studies demonstrate an improvement in cardiac function, organ perfusion, or intracellular pH.[28–31] In addition, sodium bicarbonate administration can actually have paradoxical adverse effects on intracellular pH. When bicarbonate is given by IV infusion, the carbon dioxide generated diffuses more readily than bicarbonate across cell membranes and into cerebrospinal fluid. Therefore, the intracellular pH can actually be decreased by administration of bicarbonate.[4]

CLINICAL CONTROVERSY

Although it has been recommended that sodium bicarbonate be administered to raise the arterial pH to approximately 7.20, there are no controlled clinical trials demonstrating that sodium bicarbonate administration is significantly better than general supportive care in reducing morbidity and mortality in these patients.[4,11,20–23]

Excessive sodium bicarbonate administration can result in (1) a shift of the oxyhemoglobin saturation curve to the left thereby impairing oxygen release from hemoglobin to tissues; (2) sodium and water overload, with subsequent pulmonary congestion and hypernatremia; (3) paradoxical tissue acidosis as a result of the production of CO_2 that freely diffuses into myocardial and cerebral cells[32]; and (4) decreased ionized calcium with a resultant decrease in myocardial contractility. If there is an endogenous source of bicarbonate, such as can occur in the case of ketoacidosis or lactic acidosis, a bicarbonate "overshoot" can develop because the ketoacids (acetoacetic acid and β-hydroxybutyric acid) or lactic acid are converted in the liver to bicarbonate once the underlying cause of acidosis is corrected.[10,11,33] Alkalosis can also result if too much sodium bicarbonate is administered too quickly.

If intravenous sodium bicarbonate is used, one must be mindful that the goals are to increase, not normalize, pH (to approximately 7.20) and plasma bicarbonate (to 8–10 mEq/L [8–10 mmol/L]). There is no calculative method that will assure attainment of these goals with a given dose of sodium bicarbonate because of the multiplicity of competing processes that can affect acid–base status (e.g., vomiting, potential increases in endogenous acid production, and renal failure) and the marked variability in the volume of distribution of bicarbonate (50% of body weight in patients with mild acidosis to approximately 100% in those with severe acidosis).[10,32–33] Adrogue and Madias[12] recommended that the dose of sodium bicarbonate be calculated using a distribution volume of 50% of body weight for all patients to avoid overtreatment. The total dose calculated as described previously in the RTA section should be administered as an infusion over one-half to several hours. Follow-up monitoring of arterial blood gases, beginning no sooner than 30 minutes after the end of the infusion, should be used to guide further therapeutic decisions.

Bicarbonate therapy is generally not necessary for patients with cardiac arrest, even if the initial arrest was unmonitored. The American Heart Association's Advanced Cardiac Life Support (ACLS) provider manual states that sodium bicarbonate is not useful or effective during resuscitation in hypoxic patients with lactic acidosis. Additionally, sodium bicarbonate is considered to be not useful or effective in those who are undergoing prolonged resuscitation with effective ventilation.[34] Furthermore, if sodium bicarbonate is used, it should be used only after defibrillation, cardiac compression, support of ventilation including intubation, and drug therapies such as epinephrine and antiarrhythmic agents have been employed.[35] The intial dose of sodium bicarbonate in this situation is 1 mEq/kg [1 mmol/kg]) administered by rapid, direct intravenous injection.[36] Subsequent doses of sodium bicarbonate should be based on measurements of arterial blood pH and $Paco_2$ given the propensity for it to cause alkalemia.[37]

TROMETHAMINE

THAM, available as a 0.3 N solution, is a highly alkaline, sodium-free organic amine that acts as a proton acceptor to prevent or correct acidosis.[39] THAM combines with hydrogen ions from carbonic acid to form bicarbonate and a cationic buffer. THAM also acts as an osmotic diuretic to increase urine flow, urine pH, and the excretion of fixed acids, CO_2, and electrolytes. At pH 7.4, 30% of THAM is not ionized and therefore can penetrate into cells and neutralize acidic anions of the intracellular fluid. Intracellular pH increases have been noted within 1 hour after the infusion of THAM. There is, however, no clinical or physiologic evidence that this action is beneficial, or that THAM is more efficacious than sodium bicarbonate.[28,39]

When THAM is used, it must be administered slowly, with careful monitoring to avoid alkalosis. The usual empiric dosage range for tromethamine is 1 to 5 mmol/kg administered intravenously over 1 hour, but doses up to 1.25 mmol/kg can be given over 5 to 15 minutes in acute situations. The dose of THAM can be individualized using the following equation[39]:

$$\text{Dose of THAM (in mL)} = 1.1 \times \text{BW(in kilograms)} \times \text{base deficit}$$

where base deficit = normal $[HCO_3^-]$ minus current $[HCO_3^-]$.

The need for additional THAM is determined by serial measurements of the serum bicarbonate concentration and calculation of the base deficit. Large doses can cause respiratory depression as a result of an increase in blood pH and a decrease in $Paco_2$ concentration.[38] THAM solution is highly alkaline and can cause severe inflammation, vascular spasm, or tissue damage (necrosis, sloughing, pain, chemical phlebitis, or thrombosis) if infiltration occurs. Hyperkalemia, hypoglycemia, hypocalcemia, and impaired coagulation have also been reported.[28,39] This agent should only be used with extreme caution in patients with severe liver or kidney failure.

CARBICARB

Carbicarb is an equimolar mixture of sodium carbonate (Na_2CO_3) and sodium bicarbonate ($NaHCO_3$).[39,40] Given that the carbonate ion is a stronger base than bicarbonate, Carbicarb preferentially buffers hydrogen ions resulting in the formation of bicarbonate rather than CO_2. Thus Carbicarb limits, but does not eliminate, the generation of CO_2. Unlike bicarbonate, which can produce a paradoxical intracellular acidosis and thereby impair cardiac function, Carbicarb appears to correct intracellular acidosis if present.[41,42] Despite these effects, there are no consistent data on the effects of carbicarb on hemodynamic endpoints and this agent is not available for use in humans.[28]

DICHLOROACETATE

Dichloroacetate (DCA), another investigational agent, facilitates aerobic lactate metabolism by stimulating the activity of lactate dehydrogenase, thus reversing hyperlactatemia and elevating blood pH.[43,44] DCA, when compared to conventional management in controlled studies, however, has not been shown to improve hemodynamic parameters or clinical outcomes.[43,45,46] DCA can cause mild drowsiness and peripheral neuropathy that can be ameliorated or prevented with thiamine supplementation.[44] The future role of DCA in the management of metabolic acidosis, particularly lactic acidosis, remains to be clarified.[28]

METABOLIC ALKALOSIS

Pathophysiology

Metabolic alkalosis is a simple acid–base disorder that presents as alkalemia (increased arterial pH) with an increase in plasma bicarbonate. It is an extremely common entity in hospitalized patients with acid–base disturbances. Under normal circumstances, the kidney is readily able to excrete an alkali load. Thus evaluation of patients with metabolic alkalosis must consider two separate issues: (1) the initial process that generates the metabolic alkalosis; and (2) alterations in renal function that maintain the alkalemic state.[47]

9 The generation of metabolic alkalosis can also result from excessive losses of hydrogen ion from the kidneys or stomach or from a gain secondary to the ingestion or administration of bicarbonate-rich fluids. Gastric juice, rich in chloride and hydrogen ion, is secreted at a rate of less than 50 mL/h in the basal state, but can increase up to five-fold with stimulation.[8] In the gastric parietal cells, hydrogen ion and bicarbonate are generated from CO_2 and water.[47] The hydrogen ion is secreted into gastric fluid, and the bicarbonate is retained in the ECF. Normally, an amount of bicarbonate equal to the bicarbonate generated in the stomach is eliminated in the alkaline pancreatic and small-bowel secretions, maintaining hydrogen ion balance. With vomiting and nasogastric suctioning, hydrogen ion is lost externally and metabolic alkalosis results. Diarrhea, as seen with secretory villous adenomas and other secretory diarrheas, often results in excessive gastrointestinal losses of chloride-rich, bicarbonate-poor fluid and thus leads to the generation of metabolic alkalosis.

10 Diuretic agents acting on the thick ascending limb of the loop of Henle (e.g., furosemide, bumetanide, and torsemide) and distal convoluted tubule (e.g., thiazides), have most commonly been associated with the generation of metabolic alkalosis.[48] These agents promote the excretion of sodium and potassium almost exclusively in association with chloride, without a proportionate increase in bicarbonate excretion. Collecting duct hydrogen ion secretion is stimulated directly by the increased luminal flow rate and sodium delivery, and indirectly by intravascular volume contraction, which results in secondary hyperaldosteronism. Renal ammoniagenesis can also be stimulated by concomitant hypokalemia, further augmenting net acid excretion.

Increased renal acid excretion can also be the result of excess mineralocorticoid activity. Elevated mineralocorticoid levels directly stimulate collecting duct hydrogen ion secretion and indirectly increase ammoniagenesis by causing hypokalemia.[47] Increased mineralocorticoid activity can result from Cushing syndrome, primary hyperaldosteronism, or hyperaldosteronism secondary to increased renin activity (e.g., malignant hypertension). In Bartter and Gitelman syndromes, defects in sodium transport in the loop of Henle (Bartter) or distal convoluted tubule (Gitelman) lead to hypokalemia, secondary hyperaldosteronism, and metabolic alkalosis.[47] In Liddle's syndrome, enhanced sodium reabsorption by the cortical collecting duct epithelial sodium channel results in a syndrome of pseudohyperaldosteronism.[47] Administration of high doses of penicillins (e.g., ticarcillin) can produce metabolic alkalosis because they act as nonreabsorbable anions. High concentrations of poorly reabsorbable anions in the distal renal tubule increase luminal flow rate and luminal electronegativity, which enhances the secretion of potassium and hydrogen ion and results in hypokalemia and metabolic alkalosis.

Metabolic alkalosis can also be generated by the gain of exogenous alkali. This can be seen as a result of bicarbonate administration or from the infusion of organic anions that are metabolized to bicarbonate, such as acetate, lactate, and citrate. The milk-alkali syndrome was historically a common cause of metabolic alkalosis in patients with peptic ulcer disease secondary to the ingestion of large quantities of milk products and antacids. With the advent of alternative therapies for dyspeptic syndromes that are far more effective than milk, this syndrome is now rarely seen.

TABLE 61-10 Causes of Metabolic Alkalosis Differentiated on the Basis of Their Responsiveness to Sodium Chloride

Sodium chloride–responsive (urinary chloride concentration <10 mEq/L [<10 mmol/L])
Gastrointestinal disorders
Vomiting
Gastric drainage
Villous adenoma of the colon
Chloride diarrhea
Diuretic therapy
Correction of chronic hypercapnia
Cystic fibrosis
Excessive bicarbonate therapy of an organic acidosis
Mild/moderate potassium deficiency
Sodium chloride–resistant (urinary chloride concentration >20 mEq/L [>20 mmol/L)
Excess mineralocorticoid activity
Hyperaldosteronism
Cushing syndrome
Bartter syndrome
Gitelman syndrome
Excessive black licorice intake
Profound potassium depletion
Magnesium deficiency
Liddle syndrome
Estrogen therapy
Unclassified
Alkali administration
Milk-alkali syndrome
Massive blood or plasma protein fraction transfusion
Nonparathyroid hypercalcemia
Carbohydrate refeeding after starvation
Large doses of penicillin

Metabolic alkalosis is predominantly maintained because of an abnormality in renal function. Normally, the kidneys are capable of excreting all of the excess bicarbonate presented to them, even during periods of increased bicarbonate loads.[4] As the serum bicarbonate concentration increases, the filtered bicarbonate load exceeds the maximal rate for bicarbonate reabsorption, and the excess bicarbonate is excreted in the urine. Under normal circumstances, the excess bicarbonate is rapidly excreted, and metabolic alkalosis does not occur or is corrected in a matter of hours.[47]

11 Several mechanisms can impair renal bicarbonate excretion and contribute to the maintenance phase of metabolic alkalosis.[47] In general, these mechanisms can be divided into volume-mediated processes (sodium chloride–responsive) and volume-independent processes (sodium chloride–resistant) that are predominantly associated with excess mineralocorticoid activity and hypokalemia (Table 61–10). Intravascular volume depletion maintains metabolic alkalosis through a number of mechanisms. Decreases in the glomerular filtration rate reduce the filtered load of bicarbonate at any given serum concentration, thereby decreasing the kidney's ability to excrete a bicarbonate load. Although this can play a role in patients with chronic kidney disease, it is also an important factor in patients in whom intravascular volume contraction accompanies metabolic alkalosis. Decreased effective arterial blood volume also enhances proximal and distal tubular sodium reabsorption. Sodium reabsorption must be coupled with reabsorption of an anion, such as chloride or bicarbonate, or exchange with a cation, such as potassium or hydrogen, to maintain charge neutrality. In the proximal tubule, increased sodium reabsorption stimulates bicarbonate reabsorption. In the distal nephron, enhanced sodium reabsorption, particularly in the setting of hypokalemia, stimulates hydrogen ion secretion.

Mineralocorticoid excess also plays a significant role in the maintenance of metabolic alkalosis. In patients with volume-responsive

metabolic alkalosis, intravascular volume depletion stimulates aldosterone secretion. As discussed earlier, excess mineralocorticoid activity can also underlie the generation of metabolic alkalosis. In either situation, the increased mineralocorticoid effect stimulates collecting duct hydrogen ion secretion. Metabolic alkalosis can also be maintained by persistent hypokalemia, enhancing proximal tubular bicarbonate reabsorption, stimulating ammoniagenesis, and increasing distal tubular hydrogen ion secretion.[47]

Clinical Presentation

There are no unique signs or symptoms associated with mild to moderate metabolic alkalosis, but patients may complain of symptoms related to the underlying cause of the disorder (e.g., muscle weakness with hypokalemia or postural dizziness with volume depletion). They may have a history of vomiting, gastric drainage, or diuretic use, all of which contribute to the development of metabolic alkalosis. Severe alkalemia (blood pH >7.60) has been associated with cardiac arrhythmias, particularly in patients with heart disease, hyperventilation, and hypoxemia.[49] Neuromuscular irritability can be present, with signs of tetany or hyperactive reflexes, possibly caused by the decreased ionized calcium concentration that occurs secondary to the increase in pH. This decrease in ionized calcium may be caused by a conformational change in the albumin molecules to which the calcium is bound, resulting in increased binding, or by decreased competition from hydrogen ions for binding sites on the albumin molecule. Mental confusion, muscle cramping, and paresthesia can also occur. Lastly, patients will be more difficult to liberate from mechanical ventilation. (Please see metabolic alkalosis case 59 from Casebook.)

Compensation

The respiratory response to metabolic alkalosis is hypoventilation, which results in an increased $Paco_2$. Respiratory compensation is initiated within hours when the central and peripheral chemoreceptors sense an increase in pH. The $Paco_2$ increases 6 to 7 mm Hg (0.8–0.9 kPa) for each 10-mEq/L (10 mmol/L) increase in bicarbonate, up to a $Paco_2$ of approximately 50 to 60 mm Hg (6.7–8.0 kPa) (see Table 61–7) before hypoxia sensors react to prevent further hypoventilation. If the $Paco_2$ is normal or less than normal, one should consider the presence of a superimposed respiratory alkalosis, which can be secondary to fever, gram-negative sepsis, or pain.

TREATMENT

Metabolic Alkalosis

Because the body tolerates alkalemia far less well than acidemia, treatment of metabolic alkalosis is nearly always required and should be aimed at correcting the factor(s) responsible for the maintenance of the alkalosis.[23,49] For example, vomiting should be treated with antiemetics, gastric losses of hydrogen ion during nasogastric suction can be modulated by giving histamine blockers such as ranitidine or proton pump inhibitors such as omeprazole, and reducing or discontinuing diuretic therapy.[47,50] Metabolic alkalosis will persist until the renal mechanism responsible for maintaining the disorder is corrected, despite the fact that the original cause of the elevated plasma bicarbonate may have resolved. For example, hypovolemia should be treated with sodium chloride (i.e., diuretic abuse or nasogastric suction) to allow excretion of bicarbonate by the kidney. However, patients with severely compromised cardiovascular function may not be able to tolerate this therapeutic approach. In situations such as this and/or the presence of life-threatening alkalosis, some have advocated reduction in pH by control of ventilation.[4] Although controlled hypoventilation, sometimes using inspired CO_2 with supplemental oxygen to prevent hypoxia can be life-saving,[4] this approach is not universally accepted.[33] Therapy for metabolic alkalosis can be conceptualized on the basis of the sodium chloride responsiveness of the disorders as shown in Figure 61–4.

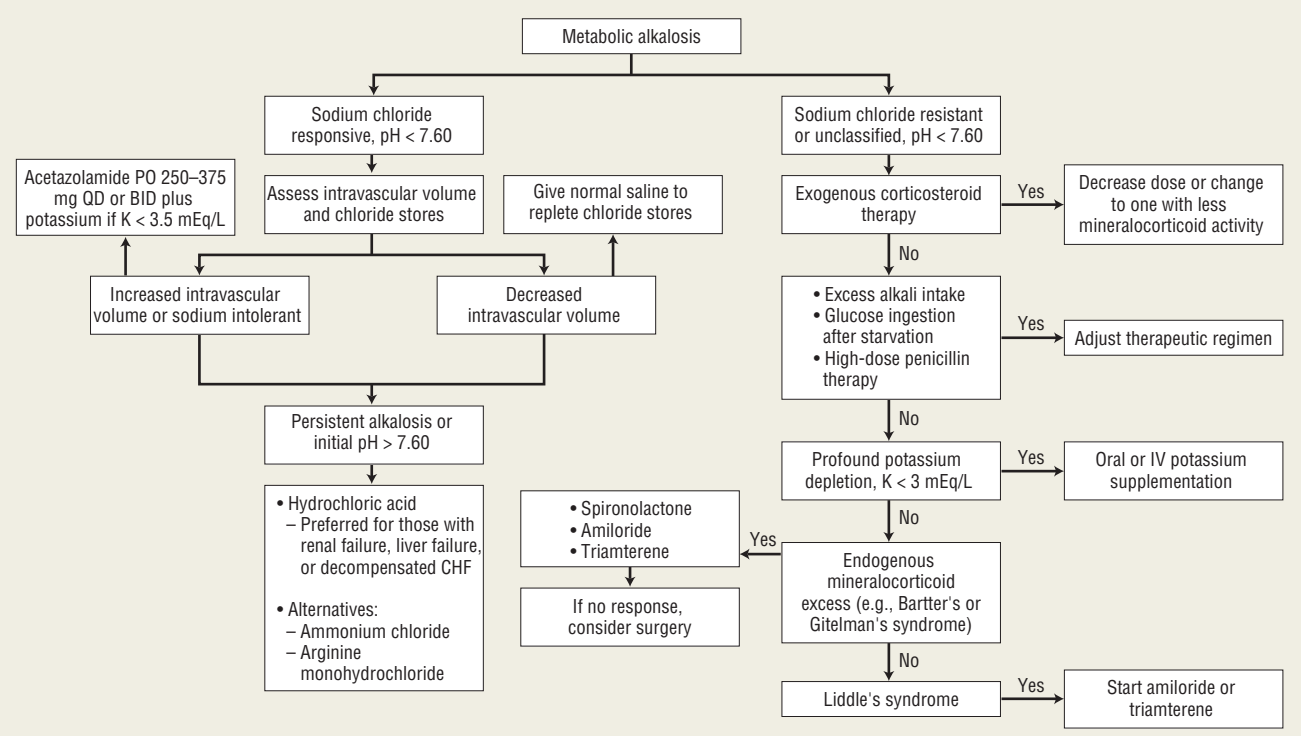

FIGURE 61-4. Treatment algorithm for patients with primary metabolic alkalosis. (BID, twice daily; CHF, chronic heart failure; K, potassium [serum potassium in mEq/L is numerically equivalent to mmol/L]; PO, orally; QD, every day.)

SODIUM CHLORIDE–RESPONSIVE DISORDERS

Sodium chloride–responsive disorders usually result from volume depletion and chloride loss, which can accompany severe vomiting, prolonged nasogastric suction, and diuretic therapy. Initially therapy is directed at expanding intravascular volume and replenishing chloride stores. Sodium and potassium chloride–containing solutions should be administered to patients who can tolerate the volume load.[47,49] Patients with metabolic alkalosis who are volume overloaded or intolerant to volume administration because of congestive heart failure can benefit from the carbonic anhydrase inhibitor acetazolamide. This agent inhibits the action of carbonic anhydrase, thereby inhibiting renal bicarbonate reabsorption. Unfortunately, it also increases the renal losses of potassium and phosphate. Administration of acetazolamide (250–375 mg once or twice daily) can promote a sufficient bicarbonate diuresis and return the pH toward normal.[57] However, because the clinical effectiveness of the drug declines as the HCO_3^- concentration decreases, only rarely will this approach fully correct the alkalosis.[47]

Acidifying agents including hydrochloric acid, ammonium chloride, and arginine monohydrochloride can be used to treat severe (pH >7.6) symptomatic metabolic alkalosis.[52] In general, this management is reserved for patients who are unresponsive to conventional fluid and electrolyte management or who are unable to tolerate the requisite volume load because of decompensated congestive heart failure or advanced renal failure.[47] Alternatively, hemodialysis using a low-bicarbonate dialysate can be used for the rapid correction of metabolic alkalosis.

HYDROCHLORIC ACID

Hydrochloric acid is usually infused intravenously via a large central vein as a 0.1 to 0.25 N HCl solution in either 5% dextrose or normal saline, although sterile water has also been used. Extemporaneously prepared solutions can be made by adding 100 to 250 mEq (100–250 mmol) of HCl through a 0.22-mm filter into a glass container of saline or dextrose. Hydrochloric acid can also be added to parenteral nutrient solutions and administered via a central line without serious degradation of proteins.[53] The rate of infusion should be 100 to 125 mL/h (10–25 mEq/h [10–25 mmol/h]), with frequent monitoring of arterial blood gases. To prevent overcorrection, the infusion should be stopped when the arterial pH decreases to 7.50.[47]

The dose of hydrochloric acid can be based on an estimate of the total body chloride deficit[36]:

$$\text{Dose HCl (in mEq or mmol)} = [0.2\ \text{L/kg} \times \text{BW(in kilograms)}] \times [103 - \text{observed serum chloride}]$$

where the estimated chloride space is 0.2 times the body weight, and the average serum chloride is 103 mEq/L (103 mmol/L). Alternatively, the dose can be calculated based on the estimated base deficit[49]:

$$\text{Dose HCl (in mEq or mmol)} = [0.5\ \text{L/kg} \times \text{BW (in kilograms)}] \times (\text{desired}[HCO_3^-] - \text{observed}[HCO_3^-])$$

CLINICAL CONTROVERSY

While some clinicians prefer the formula for estimating hydrochloric acid dose that is based on serum chloride given that it is the first formula validated for this use; other clinicians prefer the formula that uses the serum HCO_3^- given that HCO_3^- is a goal of therapy when initiating hydrochloric acid therapy.

The dose of hydrochloric acid is usually infused intravenously over 12 to 24 hours.[54] A severe transient respiratory acidosis can occur if the hydrochloric acid is infused too quickly because of a slower reduction of the elevated bicarbonate concentration in the cerebrospinal fluid than in the extracellular fluid. Improvement is usually seen within 24 hours of initiating therapy. Arterial blood gases and serum electrolytes should be drawn every 4 to 8 hours to evaluate and adjust therapy.

AMMONIUM CHLORIDE

Ammonium chloride has a limited role in the treatment of metabolic alkalosis. The liver converts ammonium chloride (NH_4Cl) to urea and free hydrochloric acid[36]:

$$2NH_4Cl + 2HCO_3^- \rightarrow CO(NH_2)_2 + CO_2 + 3H_2O + 2Cl^-$$

The dose of ammonium chloride can be calculated on the basis of the chloride deficit using the same method as for HCl and assuming that 20 g ammonium chloride will provide 374 mEq (374 mmol) of H^+. However, only one half of the calculated dose of ammonium chloride should be administered so as to avoid ammonia toxicity. Ammonium chloride is available as a 26.75% solution containing 100 mEq (100 mmol) of H^+ in 20 mL, which should be further diluted prior to administration. A dilute solution can be prepared by adding 20 mL of ammonium chloride to 500 mL of normal saline and infusing the solution at a rate of no more than 1 mEq/min (1 mmol/min). Improvement in metabolic status is usually seen within 24 hours. CNS toxicity, marked by confusion, irritability, seizures, and coma, has been associated with more rapid rates of administration. Ammonium chloride must be administered cautiously to patients with renal or hepatic impairment. In patients with hepatic dysfunction, impaired conversion of ammonia to urea can result in increased ammonia levels and worsened encephalopathy. In patients with renal failure, the increased urea synthesis can exacerbate uremic symptoms.[36]

ARGININE MONOHYDROCHLORIDE

Arginine monohydrochloride at a dose of 10 g/h given intravenously has been used to treat metabolic alkalosis, although it was never FDA approved for this purpose.[36] Like ammonium chloride, arginine must undergo metabolism by the liver to produce hydrogen ions, with a conversion of 100 g to 475 mEq (475 mmol) of H^+. Unlike ammonium chloride, arginine combines with ammonia in the body to synthesize urea; thus it can be used in patients with relative hepatic insufficiency. Patients with renal insufficiency should not receive arginine monohydrochloride because it can significantly elevate blood urea nitrogen and is associated with severe hyperkalemia.[36,47] The increase in potassium is caused by arginine-induced shifts of potassium from the intracellular to the extracellular space.

SODIUM CHLORIDE–RESISTANT DISORDERS

⓬ Management of these disorders usually consists of treatment of the underlying cause of the mineralocorticoid excess. For patients taking a corticosteroid, a dosage reduction or a switch to a corticosteroid with less mineralocorticoid activity (e.g., methylprednisolone) should be considered. Patients with an endogenous source of excess mineralocorticoid activity can require surgery or the administration of spironolactone, amiloride, or triamterene.[47,49,55]

Spironolactone is a competitive antagonist of the mineralocorticoid receptor. Amiloride and triamterene are potassium-sparing diuretics that inhibit the epithelial sodium channel in the distal

convoluted tubule and collecting duct. All three agents inhibit aldosterone-stimulated sodium reabsorption in the collecting duct. In addition, spironolactone directly inhibits aldosterone stimulation of the hydrogen ion secretory pump. Thus, most patients with mineralocorticoid excess, including Bartter and Gitelman syndromes, respond to therapy with these agents.[47,55–57] Liddle syndrome, which is a form of pseudohypoaldosteronism caused by overactivity of the epithelial sodium channel, is not responsive to spironolactone but can be treated with either amiloride or triamterene. Although experience is limited, some patients with Bartter and Gitelman syndromes may respond to nonsteroidal anti-inflammatory agents or angiotensin-converting enzyme inhibitors.[55–57] Finally, aggressive potassium repletion can correct the alkalosis in those who have not responded to the approaches outlined above.

RESPIRATORY ACID–BASE DISORDERS

As with the metabolic acid–base disturbances, there are two cardinal respiratory acid–base disturbances: respiratory acidosis and respiratory alkalosis. These disorders are generated by a primary alteration in carbon dioxide excretion, which changes the concentration of carbon dioxide, and therefore the carbonic acid concentration in body fluids. A primary reduction in $Paco_2$ causes an increase in pH (respiratory alkalosis), and a primary increase in $Paco_2$ causes a decrease in pH (respiratory acidosis). Unlike the metabolic disturbances, for which respiratory compensation is rapid, metabolic compensation for the respiratory disturbances is slow. Hence, these disturbances can be further divided into acute disorders, with a duration of minutes to hours, and where metabolic compensation has yet to occur, and chronic disorders that have been present long enough for metabolic compensation to be complete.

RESPIRATORY ALKALOSIS

Respiratory alkalosis is characterized by a primary decrease in $Paco_2$ that leads to an elevation in pH. The $Paco_2$ decreases when the excretion of CO_2 by the lungs exceeds the metabolic production of CO_2. It is the most frequently encountered acid–base disorder, occurring physiologically in normal pregnancy and in persons living at high altitudes.[59] Respiratory alkalosis also occurs frequently among hospitalized patients (Table 61–11).

TABLE 61-11 Causes of Respiratory Alkalosis

Central stimulation of respiration
Anxiety

Pneumonia
Pulmonary edema
Severe anemia
Peripheral stimulation of respiration
Pulmonary emboli
Asthma

$Paco_2$, partial pressure of carbon dioxide from arterial blood.

Pathophysiology

A decrease in $Paco_2$ occurs when ventilatory excretion exceeds metabolic production. Because endogenous production of CO_2 is relatively constant, negative CO_2 balance is primarily caused by an increase in ventilatory excretion of CO_2 (hyperventilation). The metabolic production of CO_2, however, can be increased during periods of stress or with excess carbohydrate administration (e.g., parenteral nutrition). Hyperventilation can develop from an increase in neurochemical stimulation via either central or peripheral mechanisms, or be the result of voluntary or mechanical (iatrogenic) hyperventilation.

A decrease in $Paco_2$ can occur in patients with cardiogenic, hypovolemic, or septic shock because oxygen delivery to the carotid and aortic chemoreceptors is reduced. This relative deficit in Pao_2 stimulates an increase in ventilation. The hyperventilation in sepsis is also mediated via a central mechanism. Hyperventilation-induced respiratory alkalosis with an elevation in cardiac index and hypotension without peripheral vasoconstriction can therefore be an early sign of sepsis.

Clinical Presentation

Although most patients are asymptomatic, respiratory alkalosis can cause adverse neuromuscular, cardiovascular, and gastrointestinal effects.[59] During periods of decreased $Paco_2$, there is a decrease in cerebral blood flow, which can be responsible for symptoms of light-headedness, confusion, decreased intellectual functioning, syncope, and seizures. Nausea and vomiting can occur, probably as a result of cerebral hypoxia. In severe respiratory alkalosis, cardiac arrhythmias can occur because of sensitization of the myocardium to the arrhythmogenic effects of circulating catecholamines.[2] Acute respiratory alkalosis has no effect on blood pressure or cardiac output in awake individuals. Anesthetized patients, however, can experience a decrease in both cardiac output and blood pressure, possibly owing to the lack of a tachycardic response.[59]

The concentration of serum electrolytes can also be altered secondary to the development of respiratory alkalosis. The serum chloride concentration is usually slightly increased, and serum potassium concentration can be slightly decreased. Clinically significant hypokalemia can be a consequence of extreme respiratory alkalosis, although the effect is usually very small or negligible.[2,59] Serum phosphorus concentration can decrease by as much as 1.5 to 2.0 mg/dL (0.48–0.65 mmol/L) because of the shift of inorganic phosphate into cells. Reductions in the blood ionized calcium concentration can be partially responsible for symptoms such as muscle cramps and tetany. Approximately 50% of calcium is bound to albumin, and an increase in pH results in an increase in binding.[54]

CLINICAL PRESENTATION OF RESPIRATORY ALKALOSIS

General

- The patient is usually asymptomatic if the condition is chronic and mild.

Symptoms

- The patient may complain of light-headedness, confusion, muscle cramps and tetany, and decreased intellectual functioning.
- Nausea and vomiting can occur, probably as a result of cerebral hypoxia.

Signs

- In severe respiratory alkalosis pH >7.60
- Syncope and seizures
- Cardiac arrhythmias
- Hyperventilation

Laboratory Tests

- Serum chloride concentration is usually slightly increased. Serum ionized calcium, potassium, and phosphorus concentration can be decreased.

Compensation

The initial response of the body to acute respiratory alkalosis is chemical buffering: hydrogen ions are released from the body's buffers—intracellular proteins, phosphates, and hemoglobin—and titrate down the serum bicarbonate concentration. This process occurs within minutes. Acutely, the bicarbonate concentration can be decreased by a maximum of 3 mEq/L (3 mmol/L) for each 10-mm Hg (1.3 kPa) decrease in $Paco_2$.[24] (see Table 61–7). When only physicochemical buffering has occurred, the disturbance is referred to as acute respiratory alkalosis.

Metabolic compensation occurs when respiratory alkalosis persists for more than 6 to 12 hours. In response to the alkalemia, proximal tubular bicarbonate reabsorption is inhibited, and the serum bicarbonate concentration decreases. Renal compensation is usually complete within 1 to 2 days. The renal bicarbonaturia, as well as decreased NH_4^+ and titratable acid excretion, are direct effects of the reduced $Paco_2$ and pH on renal reabsorption of chloride and bicarbonate.[2] The acuity of the respiratory alkalosis can be assessed on the basis of the degree of renal compensation (see Table 61–7). In fully compensated respiratory alkalosis, the bicarbonate concentration decreases by 4 mEq/L (4 mmol/L) below 24 for each 10-mm Hg (1.3 kPa) drop in $Paco_2$. For example, a sustained decrease in $Paco_2$ of 20 mm Hg (2.7 kPa) will lower serum bicarbonate from 24 to 14 mEq/L (24–14 mmol/L) with a resultant pH of 7.46. Bicarbonate concentrations differing from those anticipated using the preceding guidelines suggest a mixed acid–base disorder.

TREATMENT

Respiratory Alkalosis

Because most patients with respiratory alkalosis, especially chronic cases, have few or no symptoms and pH alterations are usually mild (pH not exceeding 7.50), treatment is often not required.[49] The first consideration in the treatment of acute respiratory alkalosis with pH >7.50 is the identification and correction of the underlying cause. Relief of pain, correction of hypovolemia with intravenous fluids, treatment of fever or infection, treatment of salicylate overdose, and other direct measures can prove effective. A rebreathing device, such as a paper bag, can be useful in controlling hyperventilation in patients with the anxiety/hyperventilation syndrome.[54] Oxygen therapy should be initiated in patients with severe hypoxemia. Patients with life-threatening alkalosis (pH >7.60), particularly if it is a mixed respiratory and metabolic condition and they have complications such as arrhythmia or seizures can require mechanical ventilation with sedation and/or paralysis to control hyperventilation.

Respiratory alkalosis in patients receiving mechanical ventilation is usually iatrogenic. It can often be corrected by decreasing either the set respiratory rate or tidal volume, although other measures can also be employed. The use of a capnograph and spirometer in the breathing circuit enables a more precise adjustment of the ventilator settings. Another method of treating respiratory alkalosis is to increase the amount of dead space in the ventilator circuit by placing a known length of tubing between the artificial airway and the "Y" piece of the ventilator. This results in "rebreathing" of expired gas, and therefore an increase in the inspired carbon dioxide concentration, which should increase the carbon dioxide tension of the patient, correcting the respiratory alkalosis. In patients breathing more rapidly than the ventilator settings, sedation with or without paralysis can be employed.

TABLE 61-12 Causes of Acute Respiratory Acidosis

Central
Drugs (anesthetics, opioids, sedatives)
Stroke
Head injury
Infection
Status epilepticus

Brainstem or cervical cord injury
Guillain-Barré syndrome
Myasthenia gravis
Mechanical ventilator
Ventilator malfunction
Inadequate frequency or tidal volume settings
Large dead space
Total parenteral nutrition (increased CO_2 production)

RESPIRATORY ACIDOSIS

Pathophysiology

Respiratory acidosis occurs when the lungs fail to excrete carbon dioxide resulting in a lower pH. This can be the result of conditions that centrally inhibit the respiratory center, diseases that interfere with pulmonary perfusion or neuromuscular function, and intrinsic airway or parenchymal pulmonary disease (Table 61–12). Acute respiratory acidosis with hypoxemia, hypercarbia, and acidosis is life-threatening. Those disorders that produce an increase in $Paco_2$ and hypoxemia to a degree compatible with life (e.g., chronic obstructive pulmonary disease), with or without oxygen therapy, can result in chronic respiratory acidosis (Table 61–13). These patients can function normally without noticeable neurologic

defects with $Paco_2$ concentrations in the range of 90 to 100 mm Hg (12–13.3 kPa) (normal, 40 mm Hg [5.3 kPa]), provided adequate oxygenation is maintained.[59]

Clinical Presentation

Respiratory acidosis can produce neurologic symptoms, including altered mental status, abnormal behavior, seizures, stupor, and coma. Hypercapnia can mimic stroke or CNS tumors by producing headache, papilledema, focal paresis, and abnormal reflexes. These CNS symptoms are attributable to the vasodilator effects of CO_2 in the brain that result in an increase in cerebral blood flow.[2] The CNS response to hypercapnia is extremely variable between patients and is most influenced by the acuity of presentation. Given that chronic hypercapnia blunts the usual respiratory stimulus of an elevated $Paco_2$, hypoxemia rather than hypercapnia provides the primary ventilatory stimulus in patients with severe chronic respiratory acidosis.[59]

The degree to which cardiac contractility and heart rate are altered depends on the severity of the acidosis and the rapidity with which it develops. Modest acute hypercapnia ($Paco_2$ of 50–55 mm Hg [6.7–7.3 kPa]) stimulates a stress-like response, with elevated catecholamines and corticosteroid hormone levels, and can result in increased cardiac output and pulmonary artery pressure.[59] As the severity increases, cardiac output declines and vascular resistance decreases leading to refractory hypotension in some patients.[2]

In respiratory acidosis, the serum potassium concentration increases modestly secondary to cellular shifts. The increases are less than those seen with inorganic metabolic acidosis and are difficult to predict for individual patients (see Chapter 60).

CLINICAL PRESENTATION OF RESPIRATORY ACIDOSIS

General

- The patient is usually symptomatic.

Symptoms

- The patient may complain of confusion or difficulty thinking and headache.

Signs

- In severe respiratory acidosis:
- Cardiac: Increased cardiac output if moderate that decreases if severe. Refractory hypotension can be present in some patients.
- CNS: Abnormal behavior, seizures, stupor, and coma. Papilledema, focal paresis, and abnormal reflexes can also be present.

Laboratory Tests

- Serum potassium concentration can be modestly increased. Hypercapnia can be moderate ($Paco_2$ of 50–55 mm Hg [6.7–7.3 kPa]) to severe ($Paco_2$ of >80 mm Hg [>10.6 kPa]). Hypoxia (Pao_2 is <70 mm Hg [<9.3 kPa]) is often present.

Compensation

The body responds to acute respiratory acidosis with chemical buffering. The increase in $Paco_2$ results in increased carbonic acid levels. The carbonic acid dissociates, releasing hydrogen ions, which are buffered by nonbicarbonate buffers (i.e., proteins, phosphate, and hemoglobin) and bicarbonate. Thus, on the basis of physicochemical factors, increases in $Paco_2$ raise the serum bicarbonate concentration. In general, in acute respiratory acidosis, the bicarbonate concentration increases by 1 mEq/L (1 mmol/L) above 24 for each 10-mm Hg (1.3 kPa) increase in $Paco_2$ above 40 (5.3 kPa) (see Table 61–7).

Metabolic compensation occurs when respiratory acidosis is prolonged beyond 12 to 24 hours. In response to hypercapnia and acidemia, proximal tubular bicarbonate reabsorption, ammoniagenesis, and distal tubular hydrogen secretion are enhanced, resulting in an increase in the serum bicarbonate concentration that raises the pH toward normal. Renal compensation for chronic hypercapnia generally results in the plasma bicarbonate concentration increasing by 4 mEq/L (4 mmol/L) above 24 for each 10-mm Hg (1.3 kPa) increase in $Paco_2$ above 40 (5.3 kPa) (see Table 61–7). The new steady state in acid–base values is generally achieved within 5 days of the onset of hypercapnia in dogs; the time interval necessary for compensation in humans has not been established.

TREATMENT

Respiratory Acidosis

The treatment of respiratory acidosis is dependent on the chronicity of the patient's condition. Respiratory decompensation in patients with chronic elevations in $Paco_2$ are frequently seen in those with acute infections and those recently started on narcotic analgesics or oxygen therapy.[49] Aggressive treatment of these conditions can offer considerable benefit and should be initiated. Furthermore, tranquilizers and sedatives should be avoided and supplemental oxygen, if used, should be minimized.

ACUTE RESPIRATORY ACIDOSIS

⓭ When carbon dioxide excretion is severely impaired ($Paco_2$ >80 mm Hg [>10.6 kPa]) and/or life-threatening, hypoxia is present (Pao_2 <40 mm Hg [<5.3 kPa]); the immediate therapeutic goal is to provide adequate oxygenation. Under these circumstances, hypoxia, not acidemia, is the principal threat to life. A patent airway needs to be established, which can necessitate intubation. Excessive secretions must be cleared from the airway and oxygen administered to restore adequate oxygenation. Mechanical ventilation is usually required.

The underlying cause of the acidosis should be treated aggressively (e.g., bronchodilators for treatment of severe bronchospasm; narcotic or benzodiazepine antagonists to reverse the deleterious effects of these agents on the respiratory center). Bicarbonate administration is rarely necessary in the treatment of respiratory acidosis. Furthermore, rapid correction of acidosis with bicarbonate can eliminate the patient's respiratory drive or precipitate metabolic alkalosis. Cautious use of alkali (bicarbonate or THAM) can restore the responsiveness of bronchial muscles to β-adrenergic agonists and thus can be beneficial for those patients with severe bronchospasm.[49] Arterial blood gases should be monitored closely to ensure that the respiratory acidosis is resolving without creating a metabolic alkalosis as the result of compensatory elevation in HCO_3^- and decrease in $Paco_2$. Arterial blood gases should be obtained every 2 to 4 hours during the acute phase and less frequently (every 12–24 hours) as the acidosis improves.

ACUTE RESPIRATORY ACIDOSIS IN A COMPENSATED CHRONIC RESPIRATORY ACIDOTIC PATIENT

Patients with a history of chronic respiratory acidosis (e.g., those with chronic obstructive pulmonary disease) can experience an acute worsening of their respiratory acidosis. This can result

in severe life-threatening hypoxemia. As with acute respiratory acidosis, the goals of therapy are maintenance of a patent airway and adequate oxygenation. Individuals with chronic respiratory acidosis are routinely able to tolerate a low Pao_2 and an elevated $Paco_2$ because of compensation (increased number of red blood cells, hemoglobin content, and 2,3-diphosphoglycerate). The drive to breathe in these patients is dependent on hypoxemia rather than hypercarbia. Administration of oxygen to a patient with chronic respiratory acidosis can eliminate this drive to breathe and result in the syndrome of carbon dioxide narcosis. In this case, if the Pao_2 is 50 mm Hg (6.7 kPa), no oxygen treatment is necessary. If the Pao_2 is <50 mm Hg (<6.7 kPa), oxygen therapy should be initiated carefully using a controlled flow of oxygen.[2]

Arterial blood gases should be checked periodically to ensure adequate oxygenation. If the $Paco_2$ increases during oxygen therapy, it can be a sign of impending carbon dioxide narcosis and oxygen therapy may need to be discontinued. The underlying cause of the acute exacerbation should be aggressively managed. Pulmonary infections should be treated with the appropriate antibiotics and bronchodilators administered as necessary. Excess secretions should be cleared from the airway to allow proper gas exchange. This can involve increasing oral fluid intake to decrease the viscosity of secretions, deep breathing, and postural drainage, suction, or bronchoscopy.

MIXED ACID–BASE DISORDERS

DIAGNOSIS

The diagnosis of a mixed disorder depends on an understanding of the appropriate quantitative response of the compensatory mechanisms for each of the simple acid–base disturbances. To diagnose mixed disorders, one must know how each of the four simple disorders alters pH, $Paco_2$, and $[HCO_3^-]$ (see Table 61–7). If a given set of blood gases does not decrease within the range of expected responses for a simple acid–base disturbance, a mixed disorder should be suspected. In addition to laboratory information, a thorough history and physical examination of the patient will often lead to the diagnosis, even before the laboratory data are available. Examples of common mixed disturbances follow.

Mixed Respiratory Acidosis and Metabolic Acidosis

In mixed respiratory and metabolic acidosis, there is a failure of compensation. The respiratory disorder prevents the compensatory decrease in $Paco_2$ expected in the defense against metabolic acidosis. The metabolic disorder prevents the buffering and renal mechanisms from raising the bicarbonate concentration as expected in the defense against respiratory acidosis. In the absence of these compensatory mechanisms the pH decreases markedly.

Mixed respiratory and metabolic acidosis may develop in patients with cardiorespiratory arrest, in those with chronic lung disease who are in shock, and in metabolic acidosis patients who develop respiratory failure. When treating this mixed disorder, clinicians need to respond to both the respiratory and metabolic acidosis. Improved oxygen delivery must be initiated to improve hypercarbia and hypoxia. Mechanical ventilation may be needed to reduce $Paco_2$. During the initial stage of therapy, appropriate amounts of alkali should be given to reverse the metabolic acidosis (see Treatment, Metabolic Acidosis above).

Mixed Respiratory Alkalosis and Metabolic Alkalosis

The combination of respiratory and metabolic alkalosis is the most common mixed acid–base disorder. This mixed disorder occurs frequently in critically ill surgical patients with respiratory alkalosis caused by mechanical ventilation, hypoxia, sepsis, hypotension, neurologic damage, pain, or drugs, and with metabolic alkalosis caused by vomiting or nasogastric suctioning and massive blood transfusions. It can also occur in patients with hepatic cirrhosis who hyperventilate, receive diuretics, or vomit, as well as in patients with chronic respiratory acidosis and an elevated plasma bicarbonate concentration who are placed on mechanical ventilation and undergo a rapid decrease in $Paco_2$.

The renal excretion of bicarbonate that usually occurs as compensation for the respiratory alkalosis is prevented by the complicating metabolic alkalosis. Likewise, the retention of $Paco_2$ expected to compensate for metabolic alkalosis is prevented by the primary respiratory alkalosis. The failure of compensation that occurs with mixed respiratory and metabolic alkalosis can result in a severe alkalemia.

Administration of sodium chloride and potassium chloride solutions will help correct the metabolic component of this disorder and adjustment of the ventilator and/or treatment of an underlying disorder that is causing hyperventilation can correct or ameliorate the respiratory component of this mixed disorder.

Mixed Metabolic Acidosis and Respiratory Alkalosis

This mixed disorder is often seen in patients with advanced liver disease, salicylate intoxication, and pulmonary-renal syndromes. The respiratory alkalosis will decrease the $Paco_2$ beyond the appropriate range for the respiratory compensation usually seen with metabolic acidosis. The plasma bicarbonate concentration also decreases below the level expected in compensation for a simple respiratory alkalosis. In a sense, the defense of pH for either disorder alone is enhanced; thus the pH can be normal or close to normal, with a low $Paco_2$ and a low $[HCO_3^-]$. Treatment of this disorder should be directed at the underlying cause. Because of the enhanced compensation, the pH is usually closer to normal than in either of the two simple disorders.

Mixed Metabolic Alkalosis and Respiratory Acidosis

This mixed disorder often occurs in patients with chronic obstructive pulmonary disease and chronic respiratory acidosis who are treated with salt restriction, diuretics, and possibly glucocorticoids. When diuretics are initiated, the plasma bicarbonate may increase because of increased renal bicarbonate generation and reabsorption, providing mechanisms for both generating and maintaining metabolic alkalosis. The elevated pH diminishes respiratory drive and may therefore worsen the respiratory acidosis.

Although the pH may not deviate significantly from normal, treatment may need to be initiated to maintain Pao_2 and $Paco_2$ at acceptable levels. Because it is often difficult to correctly identify this mixed disorder, it is helpful to observe the patient's response to discontinuation of diuretics and administration of sodium and potassium chloride.[2] If the patient has a simple metabolic alkalosis, the $Paco_2$ will normalize, but it will only minimally affect the $Paco_2$ if it is a mixed disorder. Treatment should be aimed at decreasing the plasma bicarbonate with sodium and potassium chloride therapy, thereby allowing the renal excretion of retained bicarbonate from the diuretic-induced metabolic alkalosis. This therapy should be used cautiously to avoid exacerbating any underlying congestive heart failure.

EVALUATION OF THERAPEUTIC OUTCOMES

Because acid–base disorders are such a common and widespread problem, pharmacists can play a key role in identifying, preventing, and properly treating acid–base abnormalities. Acid–base disorders do not occur only in the intensive care unit setting. Patients in ambulatory and

extended care settings have many chronic conditions and drug therapies that commonly affect acid–base balance. Thus pharmacists in all practice settings should use their knowledge to identify patients at high risk for developing drug-related problems which affect acid–base balance and to undertake appropriate prevention and treatment measures to improve the quality of life of the patients they care for.

ABBREVIATIONS

BW: body weight

CNS: central nervous system

DCA: dichloroacetate

ECF: extracellular fluid

H^+: hydrogen ion

HCO_3^-: bicarbonate

H_2CO_3: carbonic acid

HIV: human immunodeficiency virus

NH_4^+: ammonium

$Paco_2$: partial pressure of carbon dioxide from arterial blood

Pao_2: partial pressure of oxygen from arterial blood

pH: the negative logarithm (base 10) of the hydrogen ion concentration

p*K*: the negative logarithm of the dissociation constant

$Pvco_2$: partial pressure of carbon dioxide from venous blood

Pvo_2: partial pressure of oxygen from venous blood

RTA: renal tubular acidosis

SAG: serum anion gap

THAM: tromethamine (*Tris*[hydroxymethyl]-aminomethane)

UCs: unmeasured cations

UAs: unmeasured anions

SECTION 6
NEUROLOGIC DISORDERS

CHAPTER 62

Evaluation of Neurologic Illness

SUSAN C. FAGAN AND FENWICK T. NICHOLS

KEY CONCEPTS

1. The clinical neurologic history and examination are the cornerstones of neurologic diagnosis and management.
2. Through the patient's history one can determine the main symptoms, the mode of onset (gradual or sudden), progression over time (maximal at onset or steadily gaining intensity), and associated illnesses/risk factors.
3. The neurologic examination is directed at localization of the disease process so that evaluation and management may be planned appropriately.
4. The neurologic examination of a specific patient may be adapted to the patient's specific deficit. For example, a patient with double vision may warrant an extensive cranial nerve examination but a less extensive assessment of finger strength.

To contribute most effectively to the care of patients with neurologic illness, one must understand the tools used in the diagnosis and management of these patients. In addition, clinicians must be able to gather their own data through a targeted neurologic examination and history taking to ensure optimal pharmacotherapy in neurologic patients. Despite technologic advances that have led to the development of sensitive diagnostic tests in neuroscience, the clinical neurologic history and examination are still the cornerstones of the neurologic diagnosis and management.[1]

SIGNS AND SYMPTOMS

1 As in all of medicine, obtaining an accurate and complete history is of utmost importance in the evaluation of neurologic diseases. In many instances, the diagnosis can be made on the basis of the history, and the neurologic examination can be tailored to optimally evaluate the patient and confirm the diagnosis. The clinician depends on the patient or family for the details of the illness. Care must be taken to avoid "leading" the patient. Obtaining an accurate history may be difficult because a number of neurologic diseases may affect patients' speech and memory. 2 Through the patient's history one can determine the main symptoms, the mode of onset (gradual or sudden), progression over time (maximal at onset or steadily gaining intensity), and associated illnesses/risk factors (recent head injury from a motor vehicle accident). The physical examination is important because it can reveal evidence of systemic disease that may have affected the nervous system secondarily (e.g., a seizure in a patient with elevated temperature and stiff neck may suggest meningitis). The neurologic examination is only one component of a complete general physical examination.

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

THE NEUROLOGIC EXAMINATION

3 An assessment of patient effort is necessary to interpret the results of the neurologic examination. It can identify any abnormalities, particularly asymmetry of function, and help to localize the lesion within the nervous system (central versus peripheral and specific location within the central nervous system [CNS] or the peripheral nervous system). The neurologic examination consists of six main components: higher cortical function (mental status), cranial nerves, motor function, reflexes, sensory function, and gait. Table 62–1 describes the common approaches to assessing each of the six domains and includes examples of the diseases in which abnormal findings are common.

4 A targeted neurologic examination can be performed when a specific deficit is suspected. Table 62–2 describes the cranial nerve examination in more detail. The reader is encouraged to consult other references to better understand the intricacies of the neurologic examination. The clinician must synthesize the results of the history and physical examination to arrive at an anatomic localization of the lesion and create a differential diagnosis.

PROCEDURES USED IN THE DIAGNOSIS

In addition to the neurologic examination, certain imaging techniques and procedures may be essential in the diagnosis of neurologic disorders. Lumbar puncture is used to obtain cerebrospinal

TABLE 62-1 The Neurologic Examination

Domain	Tests Performed	Diseases
Mental status	While obtaining the history: general mental and emotional status, speech, memory, alertness, abstract reasoning, ability to follow commands (motor integration), ability to communicate	Dementias, stroke, metabolic encephalopathies
Cranial nerves	Visual acuity, visual fields, eye movements, jaw strength, corneal reflex, facial symmetry, auditory acuity, gag reflex, shoulder and neck strength	Myasthenia gravis, Parkinson's disease, stroke, amyotrophic lateral sclerosis (ALS)
Motor function	Motor strength with and without resistance, coordination (rapid alternating movements, finger-to-nose), tremors, atrophy, fasciculations	Stroke, myasthenia gravis, Parkinson's disease, ALS
Reflexes	Biceps, triceps, tendon reflexes, plantar response (Babinski sign is an upgoing toe and is abnormal), superficial cutaneous reflexes (abdominal)	Stroke, spinal cord lesions, endocrine diseases (e.g., diabetes, hypothyroidism), peripheral neuropathy
Sensory function	Asymmetry to pinprick, vibration, temperature	Stroke, peripheral neuropathy, migraine aura, diabetes, spinal cord lesions
Gait	Walking, standing (Romberg test = eyes closed, which will accentuate disequilibrium)	Stroke, Parkinson's disease, spinal cord lesions

TABLE 62-2 Cranial Nerve Function and Examples of Testing

I. Olfactory nerve. Smell: identify odors (coffee, cinnamon, lemon; test each nostril separately).
II. Optic nerve. Visual acuity: eye chart. Visual fields: peripheral vision and blind spot; funduscopic exam; pupil size and reaction; color vision (rarely done)
III. Oculomotor (cranial nerves III, IV, and VI have similar functions and are tested as a unit). Eye movements: patient is asked to watch a light as it moved up, down, and on both sides, while eye movements are observed.
IV. Trochlear. See III.
V. Trigeminal nerve. Motor: tests power of jaw opening and sideways deviation against the resistance of a hand placed against the jaw. Sensory: test corneal reflex by touching cornea (also nasal mucosa) with a wisp of cotton.
VI. Abducens. See III.
VII. Facial nerve. Observe asymmetry of face at rest or on speaking, baring teeth, raising eyebrows, or wrinkling forehead. Reflex eye closure to a threatening movement. Glabellar tap: repetitive tapping over bridge of nose–initial blinking should cease after the first few taps.
VIII. Auditory nerve. Vestibular division: observe for nystagmus, positional testing. Auditory division: test acuity with light sound; watch, whisper, rubbing of fingers close to ear.
IX. Glossopharyngeal nerve. Test for gag reflex by touching back of throat with tongue depressor; test swallowing and coughing and note any drooling or pooling of saliva. Test symmetry of palate movement on vocalizing "ah."
X. Vagus nerve. Test gag reflex as in IX.
XI. Spinal accessory nerve. Trapezius and sternomastoid muscles: test power of shrugging shoulders and turning the head to one side against resistance.
XII. Hypoglossal nerve. Motor function of tongue. Look for wasting and abnormal movements.

fluid (CSF). It is used most often as an evaluation of CNS infections such as meningitis and encephalitis, but it is also useful in subarachnoid hemorrhage, multiple sclerosis, and dementia. Opening pressure, cell count and differential, glucose concentration, total protein concentration, and culture and sensitivity are obtained routinely. A space-occupying lesion in the brain with mass effect is a relative contraindication to lumbar puncture because herniation could result. Prior to performing a lumbar puncture, the patient should be checked for papilledema, which may indicate increased intracranial pressure. The opening CSF pressure usually is less than 180 mm H_2O. Normal CSF is clear and colorless and should not contain any red blood cells or polymorphonuclear cells. The presence of up to five mononuclear cells is considered normal. Total protein in the CSF usually is 45 mg/dL or less. Protein may increase with infection, breakdown of the blood–brain barrier (e.g., tumors, stroke, and trauma), and diabetes.

Electroencephalography (EEG) records the electrical activity of the brain. The record is interpreted by observing the basic rhythms and waveforms, the symmetry of the recording, and abnormal electrical discharges. It also may be used to assess the response to photic stimulation or hyperventilation. It is used primarily in the diagnosis of seizures and may be helpful in the evaluation of patients with altered mental status. EEG also may be used to measure evoked potentials. The evoked potentials are the EEG response to repetitive stimuli (visual, auditory, or tactile) and provide information about the presence of abnormalities and disturbances (but not the cause) in the specific pathways tested.

Electromyography (EMG) and nerve conduction velocities (NCVs) are used to assess the function of the peripheral nerves, neuromuscular junction, and muscles. NCVs are measured by stimulating the nerve and recording the speed of conduction of the impulse. NCVs can be used to detect the presence of localized peripheral nerve injuries (e.g., carpal tunnel) or diffuse symmetric neuropathies (which may be inherited or acquired). EMG assesses muscle dysfunction as a result of primary muscle disease or secondary to nerve injury. This test is used to diagnose peripheral neuropathies (inherited and acquired), Guillain-Barré syndrome, myasthenia gravis, amyotrophic lateral sclerosis, radiculopathies, and muscle diseases.

The cerebral circulatory system can be imaged or evaluated in a number of different ways depending on the type and location of the abnormality suspected. Imaging techniques can be used to identify local arterial stenosis, aneurysms, or arteriovenous malformations. Atherosclerosis of the extracranial arteries, a frequent cause of stroke, can be evaluated using ultrasound (referred to as duplex sonography, carotid Doppler, or color-flow Doppler), magnetic resonance angiography (MRA), spiral computed tomographic angiography (CTA), or intraarterial angiography. The intracranial arterial circulation can be evaluated using transcranial Doppler, MRA, CTA, or intraarterial angiography. Each technique has its own advantages and disadvantages. Intraarterial angiography provides the best imaging of the smaller arteries of the cerebral circulation but is more invasive than the other measures.

Computed tomography (CT) uses x-rays to produce images of "slices" of the brain that are 1 to 10 mm in thickness. CT revolutionized the practice of neurology by allowing direct imaging of the brain anatomy. CT is currently available in most communities and is used to evaluate patients with intracranial disease. CT scans are used to identify tumors, hemorrhages, infarctions, hydrocephalus, and atrophy. Intravenous contrast agents (a contrast-enhanced scan) can be administered to enhance the image of blood vessels and areas of blood–brain barrier damage that may be caused by abscesses, other inflammatory conditions, tumors, or stroke.

Magnetic resonance imaging (MRI) uses the magnetic properties of the hydrogen atom nucleus and proton to produce computer-processed scans that provide improved anatomic detail when compared with CT scans. MRI offers the advantages of better differentiating between white and gray matter and delineating lesions close to bone (brainstem and cerebellum) and has no radiation risk;

however, it is not as readily available as CT and is more expensive. MRI has a proven advantage over CT in evaluating lesions in the posterior fossa and in detecting lesions in the white matter, such as plaques in multiple sclerosis. MRI is also useful in the diagnosis of tumors and very early ischemic stroke (diffusion-weighted imaging). Imaging of the spinal canal and its contents can be accomplished either by MRI myelography or CT myelography.

Other imaging techniques such as positron emission tomography (PET) and single-photon emission computed tomography (SPECT) are considered tests of brain function. These tests are being studied extensively in epilepsy as well as in cerebrovascular disorders, cerebral tumors, movement disorders, and dementia. PET scans use a positron-emitting isotope to display chemical activity and the rates of biologic processes within the brain. This method can assess regional metabolic changes in the brain. The expense, technical complexity (a cyclotron is needed), and limited availability of this technique limit its clinical usefulness.

SPECT scans measure radiotracer uptake by tissues and provide cross-sectional images of the brain. This technique has been used extensively to assess cerebral blood flow. Although the resolution of SPECT is not as good as PET, the availability has led to wide clinical use in disorders such as stroke, dementia, and epilepsy.

CONCLUSION

Assessment of the patient with neurologic disease is challenging. The patient by virtue of the neurologic deficit, may or may not be able to provide reliable information regarding medication history or extent of illness. The clinician must develop alternate strategies to obtain a complete data set and develop a pharmacotherapy plan. Ability to interpret and synthesize the results of the neurologic examination and other diagnostic tests will help a great deal in this quest.

CHAPTER 63

Alzheimer's Disease

PATRICIA W. SLATTUM, RUSSELL H. SWERDLOW, AND ANGELA MASSEY HILL

KEY CONCEPTS

1. Alzheimer's disease (AD) is the most common form of dementing illness, and the prevalence of AD increases with each decade of life.
2. The etiology of AD is unknown, and current pharmacotherapy neither cures nor arrests the pathophysiology.
3. Neuritic plaques and neurofibrillary tangles are the pathologic hallmarks of AD; however, the definitive cause of this disease is yet to be determined.
4. AD affects multiple areas of cognition and is characterized by a gradual onset with a slow, progressive decline.
5. A thorough physical examination (including neurologic examination), as well as laboratory and imaging studies, is required to rule out other disorders and diagnose AD before considering drug therapy.
6. Pharmacotherapy for AD focuses on impacting three domains: cognition, behavioral and psychiatric symptoms, and functional ability.
7. Nondrug therapy and social support for the patient and family are the primary treatment interventions for AD.
8. Cholinesterase inhibitors and memantine are used to treat cognitive symptoms of AD; other medications have been suggested to be beneficial because of their potential preventive or cognitive effects.
9. Appropriate management of vascular disease risk factors may reduce the risk for developing AD and may prevent the worsening of dementia in patients with AD.
10. A thorough behavioral assessment and plan with careful examination of environmental factors should be conducted before initiating drug therapy for behavioral symptoms.
11. Pharmacotherapy may reduce the total cost of treating AD by delaying cognitive decline and time to nursing home placement.

"I now begin the journey that will lead me into the sunset of my life."
Ronald Reagan

Learning objectives, review questions, and other resources can be found at **www.pharmacotherapyonline.com**.

Alzheimer's disease (AD), first characterized by Alois Alzheimer in 1907, is a gradually progressive dementia affecting cognition, behavior, and functional status. The exact pathophysiologic mechanisms underlying AD are not entirely known, and no cure exists.[1] Although drugs may reduce AD symptoms for a time, the disease is eventually fatal.

AD profoundly affects the family as well as the patient. The need for supervision and assistance increases until the late stages of the disease, when AD patients become totally dependent on a family member, spouse, or other caregiver for all of their basic needs. These are the all-too-common experiences of the millions of people in the United States who care for someone with AD.

EPIDEMIOLOGY

1 AD is the most common cause of dementia, accounting for 50% to 60% of cases of late-life cognitive dysfunction. Its prevalence among dementia patients increases to 80% if AD lesions in conjunction with other pathologic brain lesions are considered.[2] Table 63–1 lists the most common types of dementia among older adults. Dementia in an individual can result from multiple etiologies. This chapter focuses exclusively on dementia of the Alzheimer's type. However, the reader is encouraged to use the nonpharmacologic approaches and management of behavioral problems outlined in this chapter as a general treatment approach for other types of dementia that may share similar features with AD.

Approximately 5.3 million Americans have AD.[3,4] By the year 2050, 1 in 5 people will be older than age 65 years, and the number of AD patients is projected to be 13.2 million (Fig. 63–1). Most cases present in persons older than age 65 years, but approximately 5% of cases occur in persons younger than age 65 years. Onset can be as early as age 40 years, resulting in the arbitrary age classifications of early onset (age 40–64 years) and late onset (age 65 years and older).[4,5]

Increasing age is the greatest risk factor for AD.[4] The prevalence of AD increases exponentially with age, affecting approximately 7% of individuals age 65 to 74 years, 53% of those age 75 to 84 years, and 40% of persons age 85 years and older.[3] Genetic inheritance is also a significant risk factor, although other factors may contribute. Factors determining age of onset and rate of progression remain largely undefined.

TABLE 63-1 Common Types of Dementia in Late Life

Alzheimer's disease
Vascular dementia
Lewy body dementia
Frontotemporal dementia, including Pick's disease
Reversible causes of dementia (e.g., normal-pressure hydrocephalus, thyroid dysfunction, vitamin B_{12} deficiency, depression)

Data from Reisberg,[90] Rubin,[47] and Chapman et al.[91]

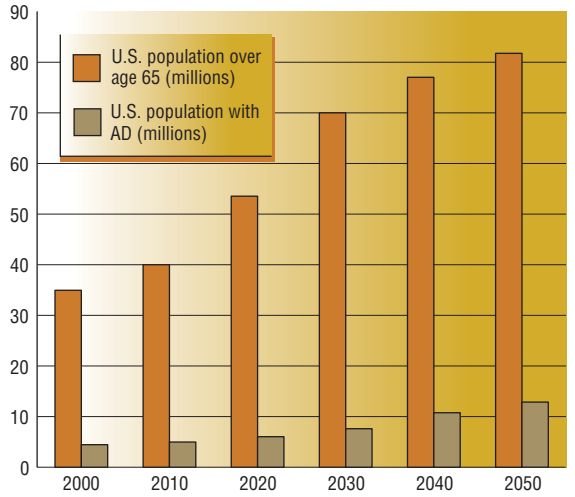

FIGURE 63-1. Our aging population. The percentage of U.S. population older than age 65 years and the percentage with AD projected from years 2000 to 2050. (*Estimates based on data from references 88 and 89.*)

Survival following AD diagnosis is typically 4 to 6 years.[4] AD is the fifth leading cause of death for those age 65 years and older in the United States.[4] AD may not cause death directly. The most common cause of death in patients with AD is pneumonia, possibly resulting from eating problems in the terminal stage of the disease.[6,7]

ETIOLOGY AND GENETICS

2 The exact etiology of AD is unknown; however, several genetic and environmental factors have been explored as potential causes of AD. Dominantly inherited forms of AD account for less than 1% of cases.[4,8] More than half of early-onset, dominantly inherited cases of AD can be attributed to alterations on chromosomes 1, 14, or 21. The majority and most aggressive early-onset cases are attributed to mutations of a gene located on chromosome 14, which produces a protein called presenilin 1.[5] A structurally similar protein, presenilin 2, is produced by a gene on chromosome 1. Both presenilin 1 and presenilin 2 encode for membrane proteins that may be involved in amyloid precursor protein (APP) processing. Scientists have identified more than 160 mutations in presenilin genes, and these mutations appear to result in reduced activity of γ-secretase, an enzyme important in β-amyloid peptide (βAP) formation.[5] APP is encoded on chromosome 21. Only a small number of early-onset familial AD cases have been associated with mutations in the *APP* gene, resulting in overproduction of βAP or an increase in the proportion of βAP ending at residue 42.[5]

Genetic susceptibility to sporadic, late-onset AD is thought to be primarily linked to the apolipoprotein E (*APOE*) genotype.[5,8,9] Thus far, the contribution of other candidate genes appears to be minor, although AD may be a heterogeneous disease resulting from complex interactions among multiple susceptibility genes and environmental factors. The gene responsible for the production of *APOE* is located on chromosome 19. There are three major subtypes or alleles of *APOE* (e.g., **2*, **3*, and **4*). Humans inherit one copy of the *APOE* gene from each parent. Inheritance of the *APOE*4* allele is believed to account for much of the genetic risk in sporadic AD. The mechanism through which *APOE*4* confers an increased risk is unknown, although *APOE*4* is associated with other factors that may contribute to AD pathology, such as abnormalities in mitochondria, cytoskeletal dysfunction, and low glucose usage.[5] The risk for AD is 2- to 3-fold higher in individuals with one *APOE*4* allele and 12-fold higher in individuals with two *APOE*4* alleles compared to those with no *APOE*4* alleles.[9] Moreover, onset of symptoms occurs at a relatively younger age as compared with patients having zero or only one copy of *APOE*4* in their genotype.[9] The strength of association is not the same across all races however.[1] Although inheritance of the *APOE*4* allele increases the risk of AD, it is not diagnostic or even essential for disease presence.

Genetic factors have been linked to both early- and late-onset AD. Alterations to chromosomes 1, 14, and 21 are associated with early-onset AD, whereas the presence of *APOE*4* alleles increases risk of developing late-onset AD. Genetic explanatory factors continue to be investigated.[5,8] However, genetic causes of AD have been directly associated with only a small percentage of Alzheimer's patients, and the exact cause of AD remains unknown.

ENVIRONMENTAL AND OTHER FACTORS

A number of environmental factors are associated with an increased risk of AD, including age, decreased reserve capacity of the brain (reduced brain size, low educational level, and reduced mental and physical activity in late life), head injury, Down syndrome, depression, herpes simplex, and risk factors for vascular disease (hypercholesterolemia, hypertension, atherosclerosis, coronary heart disease, elevated homocysteine, obesity, and diabetes).[1,4] Whether these vascular risk factors are true causal risk factors for AD contributing to AD pathology, or whether they result in cerebrovascular pathology that, in turn, contributes to the symptoms of AD, remains to be established.

The incidence of AD rises with increasing age, so that among centenarians the histopathologic and clinical changes needed to justify a diagnosis of AD probably coexist in more than 90% of these individuals.[10–12] One oft-quoted study concluded that almost half those older than age 85 years have AD.[13] AD may develop in individuals over the course of decades,[14,15] suggesting that AD is a disease most people are in the process of developing throughout adulthood. The debate about whether tangle-and-plaque dementia is a distinct disease or part of aging remains unresolved. An in-depth discussion of the aging—AD controversy is not possible in this chapter; it is reviewed elsewhere.[16,17]

PATHOPHYSIOLOGY

3 The signature lesions in AD are neuritic plaques and neurofibrillary tangles (NFTs) located in the cortical areas and medial temporal lobe structures of the brain.[1] Along with these lesions, degeneration of neurons and synapses, as well as cortical atrophy occurs. Plaques and NFTs may also be present in other diseases, even in normal aging, but at least in younger demographics there tends to be a higher burden of plaques and NFTs in AD-affected subjects than there is in age-matched controls. Several mechanisms have been proposed to explain changes in the brain that result in the symptoms of AD, including misfolding of proteins (βAP aggregation and deposition leading to the formation of plaques and hyperphosphorylation of tau protein leading to NFT development); synaptic failure and depletion of neurotrophin and neurotransimitters; and mitochondrial dysfunction (oxidative stress, impaired insulin signaling in the brain, vascular injury, inflammatory processes, loss of calcium regulation, and defects in cholesterol metabolism).[2]

AMYLOID CASCADE HYPOTHESIS

Neuritic plaques (also termed amyloid or senile plaques) are extracellular lesions found in the brain and cerebral vasculature. Plaques from AD brains largely consist of a protein called β-amyloid

protein (Aβ). Aβ peptides consisting of 36 to 43 amino acids are produced via processing of a larger protein, APP. $A\beta_{42}$ is less common than other Aβ peptides, but is prone to aggregation and plaque formation.[2] The amyloid cascade hypothesis states that there is an imbalance between the production and clearance of Aβ peptides resulting in aggregation that causes accumulation of Aβ and ultimately leading to AD.[2] Studies on the genetic forms of AD, including early-onset AD and Down syndrome led to the formulation of the amyloid cascade hypothesis. The amyloid cascade hypothesis has substantially evolved since it was initially proposed. While Aβ sequestered in plaques was at first believed to represent the critical toxic species, more recent versions of the hypothesis assume Aβ that is not sequestered in plaques actually drives the disease.[2] Even so, the amyloid cascade hypothesis seems most applicable in cases of early-onset, autosomal dominant AD. However, such cases comprise less than 1% of AD, and it is not clear whether it is reasonable to etiologically extrapolate to the late-onset form (which afflicts the vast majority of those affected). Whether individuals with late-onset AD also carry genetic variations that promote a primary Aβ amyloidosis remains to be shown. If this turns out not to be the case, the possibility that amyloidosis in late-onset AD is secondary to a more upstream event will require consideration. Before this conceptual conundrum is laid to rest, however, the amyloid cascade hypothesis will likely undergo a therapy-based practical test. If treatments that efficiently reduce βAP production or remove brain βAP fail to arrest disease progression, it would argue amyloidosis is not the primary pathology in most of those with AD.

NEUROFIBRILLARY TANGLES

As Aβ was being identified in plaques, other researchers showed that NFTs are commonly found in the cells of the hippocampus and cerebral cortex in persons with AD and are composed of abnormally hyperphosphorylated tau protein. Tau protein provides structural support to microtubules, the cell's transportation and skeletal support system.[2] When tau filaments undergo abnormal phosphorylation at a specific site, they cannot bind effectively to microtubules, and the microtubules collapse. Without an intact system of microtubules, the cell cannot function properly and eventually dies. The density of the NFTs correlates well with the severity of the dementia, because they are a hallmark of neuronal death.[2] NFTs are found in other dementing illnesses besides AD, and may represent a common method by which various inciting factors culminate in cell death.[2]

INFLAMMATORY MEDIATORS

Inflammatory or immunologic paradigms are often viewed as a corollary of the amyloid cascade hypothesis. Certainly, brain amyloid deposition associates with local inflammatory and immunologic alterations. This line of observation led some to propose that inflammation is relevant to AD neurodegeneration.[2] The inflammatory/immunologic hypotheses argue that although Aβ may have direct neurotoxicity, at least some of its toxicity might actually be an indirect consequence of an Aβ protofibril-induced microglia activation and astrocyte recruitment. This inflammatory response may represent an attempt to clear amyloid deposition. However, it is also associated with release of cytokines, nitric oxide, and other radical species, and complement factors that can both injure neurons and promote ongoing inflammation.[2] Indeed, levels of multiple cytokines and chemokines are elevated in AD brains, and certain proinflammatory gene polymorphisms are reported to be associated with AD.[2]

Consistent with these molecular observations are epidemiologic data suggesting that exposure to nonsteroidal antiinflammatory drugs (NSAIDs) may reduce AD risk.[18,19] However, multiple prospective short duration trials of NSAIDs in AD prevention and of NSAIDs as AD treatment have been therapeutically disappointing.[2] Interestingly, the conceptual impetus for trying NSAIDs in AD has radically shifted in recent years. Rather than postulate that clinical benefits (if any are shown to exist) might derive from an antiinflammatory effect, current thinking is that any observed benefits would reflect the ability of some NSAIDs to alter APP processing away from its 42-amino-acid degradation product ($A\beta_{42}$).

THE CHOLINERGIC HYPOTHESIS

Multiple neuronal pathways are destroyed in AD. Neuronal damage can be seen in conjunction with plaque structures.[2] Widespread cell dysfunction or degeneration results in a variety of neurotransmitter deficits, with cholinergic abnormalities being the most prominent.[2] Loss of cholinergic activity correlates with AD severity. In late AD, the number of cholinergic neurons is reduced, and there is loss of nicotinic receptors in the hippocampus and cortex. Presynaptic nicotinic receptors control the release of acetylcholine, as well as other neurotransmitters important for memory and mood, including glutamate, serotonin, and norepinephrine.[2]

The discovery of vast cholinergic cell loss led to the development of a cholinergic hypothesis linked to the pathophysiology of AD. The cholinergic hypothesis targeted cholinergic cell loss as the source of memory and cognitive impairment in AD. Consequently, it was presumed that increasing cholinergic function would improve symptoms of memory loss. This approach is flawed for two reasons. First, cholinergic cell loss appears to be a secondary consequence of Alzheimer's pathology, not the disease-producing event; second, cholinergic neurons are only one of many neuronal pathways destroyed in AD. It is increasingly clear that simple addition of acetylcholine cannot compensate for the loss of neurons, receptors, and other neurotransmitters lost during the course of the illness. Thus the goal is to minimize or improve symptoms through augmentation of neurotransmission at remaining synapses.

OTHER NEUROTRANSMITTER ABNORMALITIES

Although the cholinergic system has received particular attention in AD pharmaceutical research, deficits also exist in other neuronal pathways. For example, serotonergic neurons of the raphe nuclei and noradrenergic cells of the locus ceruleus are lost, while monoamine oxidase type B activity is increased. Monoamine oxidase type B is found predominantly in the brain and in platelets, and is responsible for metabolizing dopamine. In addition, abnormalities appear in glutamate pathways of the cortex and limbic structures, where a loss of neurons leads to a focus on excitotoxicity models as possible contributing factors to AD pathology.

Glutamate is the major excitatory neurotransmitter in the cortex and hippocampus. Many neuronal pathways essential to learning and memory use glutamate as a neurotransmitter, including the pyramidal neurons (a layer of neurons with long axons carrying information out of the cortex), hippocampus, and entorhinal cortex. Glutamate and other excitatory amino acid neurotransmitters have been implicated as potential neurotoxins in AD.[20] In experimental models if glutamate is allowed to remain in the synapse for extended periods of time, it can destroy nerve cells. Toxic effects are thought to be mediated through increased intracellular calcium and accumulation of intracellular free radicals.[20] Dysregulated glutamate activity is thought to be one of the primary mediators of neuronal injury after stroke or acute brain injury. Although intimately involved in cell injury, the role of excitatory amino acids in AD is as yet unclear; however, blockade of *N*-methyl-D-aspartate (NMDA)

receptors decreases activity of glutamate in the synapse and may hypothetically lessen the degree of cellular injury in AD.

BRAIN VASCULAR DISEASE AND HIGH CHOLESTEROL

There is growing evidence of a causal association between cardiovascular disease and its risk factors and the incidence of AD. Cardiovascular risk factors that are also risk factors for dementia include hypertension, elevated low-density lipoprotein cholesterol, low high-density lipoprotein cholesterol, and, particularly, diabetes.[21] Brain vascular disease may augment the cognitive impairment observed for a given amount of AD pathology in the brain. Dysfunctional blood vessels may impair nutrient delivery to neurons and reduce clearance of Aβ from the brain.[2] In addition, vascular disease may accelerate amyloid deposition and increase amyloid toxicity to neurons.[44] Controlling high blood pressure is associated with reduced rate of progression of dementia.[45] Diabetes may increase the risk of dementia through factors related to "metabolic syndrome" (dyslipidemia and hypertension), effects of potentially toxic glucose metabolites on the brain and vasculature, and through insulin itself.[21] Disturbances in insulin-signaling pathways, both in the periphery and the brain, have been linked to AD. Insulin may also regulate the metabolism of Aβ and tau protein.[2]

Research has found multiple links between cholesterol and the occurrence of AD. Apolipoprotein E is a lipoprotein that is synthesized in the liver, central nervous system, and cerebrospinal fluid. It is responsible for transporting cholesterol in the blood through the brain. It is carried by low-density lipoprotein into neurons and binds to NFTs. Apo E4 is associated with increasing deposition of Aβ and is thought to act as an accelerating modulator in the course of vascular dementia. The elevated cholesterol levels in brain neurons may alter membrane functioning and result in the cascade leading to plaque formation and AD.

OTHER MECHANISMS

Other hypotheses proposed to explain AD pathogenesis include oxidative stress, mitochondrial dysfunction, and postmenopausal loss of estrogen in women. Each of these mechanisms may contribute to AD pathogenesis, but the extent of the contribution is uncertain. There is a growing body of evidence of a role for oxidative stress and the accumulation of free radicals in the brain of AD patients.[2] Some epidemiologic studies suggest vitamin E, and possibly the combination of vitamin E and vitamin C, may reduce AD risk while others do not.[2] Mitochondrial dysfunction may result in disruption of energy metabolism in the neuron.[2] Estrogen is thought to be involved in promoting neuronal growth, and in preventing oxidative damage, which would benefit cells exposed to Aβ.[22] Estrogen receptors are present in the brain, and are distributed in a pattern consistent with areas destroyed in AD.[22] Estrogen may be important in maintaining normal cholinergic neurotransmission.[22] Estrogen may also increase NMDA receptor numbers in brain areas involved in recording new memories and prevent cell damage by acting as an antioxidant.[22] Additional mechanisms postulated for estrogen's involvement in maintaining memory function are related to the fact that it increases cerebral blood flow and glucose use, reduces plasma levels of Apo E, and blunts stress-related glucocorticoid release. Postmenopausal loss of estrogen may, therefore, impact maintenance of memory functions.

A single common mechanism for producing AD does not exist. Regardless of the source, however, the features remain the same: degeneration of neurons in higher brain areas; accumulation of NFTs and neuritic plaques; profound destruction of cholinergic pathways; and an insidious dementia, slowly progressive until death.

TABLE 63-2 Stages of Alzheimer's Disease

Mild (MMSE score 26–18)	Patient has difficulty remembering recent events. Ability to manage finances, prepare food, and carry out other household activities declines. May get lost while driving. Begins to withdraw from difficult tasks and to give up hobbies. May deny memory problems.
Moderate (MMSE score 17–10)	Patient requires assistance with activities of daily living. Frequently disoriented with regard to time (date, year, season). Recall for recent events is severely impaired. May forget some details of past life and names of family and friends. Functioning may fluctuate from day to day. Patient generally denies problems. May become suspicious or tearful. Loses ability to drive safely. Agitation, paranoia, and delusions are common.
Severe (MMSE score 9–0)	Patient loses ability to speak, walk, and feed self. Incontinent of urine and feces. Requires care 24 hours a day, 7 days a week.

MMSE, Mini-Mental Status Examination.
Data from Burns and Iliffe,[1] Alzheimer's Association,[4] Rubin.[47]

CLINICAL PRESENTATION OF ALZHEIMER'S DISEASE

4 The onset of AD is almost imperceptible, without abrupt changes in cognition or function. Deficits occur progressively over time, affecting multiple areas of cognition.[1,4] For treatment and assessment purposes, it is helpful to divide Alzheimer's symptoms into two basic categories: cognitive symptoms and noncognitive (behavioral) symptoms. Cognitive symptoms are present throughout the illness, whereas behavioral symptoms are less predictable. Table 63–2 summarizes the stages of AD.

CLINICAL PRESENTATION OF ALZHEIMER'S DISEASE

General

- The patient may have vague memory complaints initially, or the patient's significant other may report that the patient is "forgetful." Cognitive decline is gradual over the course of illness. Behavioral disturbances may be present in moderate stages. Loss of daily function is common in advanced stages.

Symptoms

Cognitive

- Memory loss (poor recall and losing items)
- Aphasia (circumlocution and anomia)
- Apraxia
- Agnosia
- Disorientation (impaired perception of time and unable to recognize familiar people)
- Impaired executive function

Noncognitive

- Depression, psychotic symptoms (hallucinations and delusions)
- Behavioral disturbances (physical and verbal aggression, motor hyperactivity, uncooperativeness, wandering, repetitive mannerisms and activities, and combativeness)

Functional

- Inability to care for self (dressing, bathing, toileting, and eating)

Laboratory Tests

- Rule out vitamin B_{12} and folate deficiency
- Rule out hypothyroidism with thyroid function tests
- Blood cell counts, serum electrolytes, liver function tests

Other Diagnostic Tests

- CT or MRI scans may aid diagnosis

DIAGNOSIS

A family member often first brings memory complaints to the attention of a primary care clinician. Up to 50% of patients who meet criteria for dementia are not given a diagnosis in the primary care setting, leading some to believe that an appropriate screening tool may be helpful in aiding diagnosis and leading to earlier treatment.[23,24] Despite the phenomenon of underdiagnosis, the United States Preventative Services Task Force concluded that there are insufficient data to recommend for or against cognitive screening for AD, because it could not be determined if the benefits outweigh the risks.[23]

Until recently the only way to confirm a clinical diagnosis of AD was through direct examination of brain tissue at autopsy or biopsy, although the recent development of in vivo plaque detection methods may change this. Several criteria have been developed for the detection and diagnosis of dementia, including the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision (DSM-IV-TR) criteria,[25] the Agency for Healthcare Research and Quality (AHRQ) Guidelines,[26] the American Academy of Neurology Guidelines,[27] the National Institute of Neurological Disorders and Stroke (NINDS) criteria,[28] and the National Institute of Neurological Communicative Disorders and Stroke (NINCDS) and the Alzheimer's Disease and Related Disorders Association (ADRDA) Criteria.[29]

AD is still primarily a clinical diagnosis.[4] The patient's examination should suggest that cognitive decline from a previously higher baseline has occurred. The history should corroborate this, and further indicate cognitive decline has reached the point where changes in social or occupational functioning are present. It is possible to administer a sophisticated exam that defines cognitive domain strengths and weaknesses, and enables a neuroanatomic localization of the observed deficits. Ideally, evidence of defective retention memory (amnesia) will implicate bimesiotemporal dysfunction. Evidence of parietal cortical dysfunction (visuospatial dysfunction), dorsolateral prefrontal dysfunction (executive dysfunction), or lateral temporal dysfunction (language dysfunction) should also be present. When approached in this way, the exam can indicate a pattern of cognitive decline that is consistent with what would be expected in AD, and assist with rendering a diagnosis that is as much a diagnosis of inclusion as it is of exclusion.

Objectively defining social or occupational dysfunction can prove tricky in the older patient who may be retired, and who may also lead a socially restricted lifestyle for reasons of frailty. For such patients, the minimal requirement is to establish a change in activities of daily living. Early on, this usually involves a change in instrumental activities of daily living (handling finances, organizing medications) rather than basic activities of daily living (hygiene, dressing). Some AD subspecialists use a detailed, standardized, semistructured interview of a nonpatient informant as the most critical piece of the diagnostic evaluation.[30]

Almost any medication can contribute to cognitive impairment in vulnerable individuals, but certain classes of medication are more commonly implicated. Benzodiazepines and other sedative hypnotics, anticholinergics, opioid analgesics, antipsychotics, and anticonvulsants have been associated with cognitive impairment.[31,32] NSAIDs, histamine H_2-receptor antagonists, digoxin, amiodarone, antihypertensives, and corticosteroids have been implicated in cases of delirium.[31] Because medications are a reversible cause of cognitive symptoms, medication review and management are essential.

5 For patients who meet criteria for the dementia syndrome (whether the underlying cause is ultimately felt to be AD or not), current recommendations from the American Academy of Neurology include a neuroimaging study (computed tomography or magnetic resonance imaging), as well as a serologic evaluation that includes blood cell counts, serum electrolytes, liver function tests, a test of thyroid function, and a vitamin B_{12} level.[27] Earlier guidelines included a serologic test for syphilis, but this requirement has since been downgraded to optional. When circumstances suggest AD is not the leading entity on the differential diagnosis, other neurologic tests such as spinal fluid analysis or electroencephalogram can occasionally be justified. Neuropsychological testing is also optional, but can prove quite useful for the diagnosis of AD by helping to establish a neuroanatomical localization for the patient's cognitive deficits.

Efforts to define the role of other AD diagnostic tests are ongoing. Positron emission tomography scanning may reveal a pattern of hypometabolism typical of AD (bitemporoparietal hypometabolism), but by itself the diagnostic accuracy of positron emission tomography scanning still lags behind that of the clinical examination and history.[33] *APOE* genotyping by itself is also insufficient to make or break a diagnosis of AD, but demonstrating an *APOE*4* allele in a suspected patient increases the specificity of the diagnosis and can help predict which patients with mild cognitive impairment are most likely to progress to a full-blown diagnosis of AD over the next several years.[34] Unless the patient developed dementia prior to age 60 years and also had a parent that developed AD before age 60 years, presenilin 1, presenilin 2, or *APP* genotyping is usually not indicated.

MILD COGNITIVE IMPAIRMENT

It has long been recognized that aging individuals experience changes in cognitive function. Mild cognitive impairment (MCI) constitutes a syndromic designation that categorizes patients with cognitive complaints insufficient to warrant a diagnosis of dementia. Persons diagnosed with MCI carry a 10% to 15% chance per year of progressing to an AD diagnosis.[35] A logical extension of this is that what clinicians are actually seeing in most people with MCI is the initial manifestation of a progressive degenerative dementia that will eventually meet AD diagnostic criteria.[1,35] However, it is important to note that not everyone meeting MCI criteria does or will have AD. As the MCI designation is increasingly applied, MCI criteria continue to evolve.[35]

TREATMENT

Alzheimer's Disease

DESIRED OUTCOMES

6 The primary goal of treatment in AD is to symptomatically treat cognitive difficulties and preserve patient function as long as possible. Secondary goals include treating the psychiatric and behavioral sequelae that occur as a result of the disease. Current AD treatments have not been shown to prolong life, cure AD, or halt or reverse the pathophysiologic processes of the disorder.[36]

GENERAL TREATMENT APPROACH

Clinical trials have consistently demonstrated modest benefits of early and continuous treatment with cholinesterase inhibitors.[36] Memantine added in moderate to severe disease may also provide benefit. Following this approach allows for maximum gain and maintenance of cognition and activities of daily living. A symptomatic approach is used to treat behavioral symptoms as they arise.

Provision of education to the patient and family at the time of diagnosis, including discussion of the course of illness, realistic expectations of treatment, and the importance of legal and financial planning, are essential to appropriate treatment. Good communication skills are important to maintain a therapeutic environment and minimize stress throughout the course of illness.

NONPHARMACOLOGIC THERAPY

7 AD has a profound effect on both the patient and family, so appropriate treatment, both nonpharmacologic and pharmacologic, is needed. Nonmedication interventions are the current primary interventions for management of AD, and medications should be used in the context of multimodal interventions. Behavioral and psychiatric symptoms are among the most challenging and distressing symptoms of the disease and may be the determining factor in a family's decision to seek institutional care. Symptoms such as sleep disturbances, wandering, urinary incontinence, agitation, and aggression in patients with dementia are best managed using behavioral interventions rather than medications whenever possible.[37,38]

Upon initial diagnosis, the patient and caregiver should be educated on the course of illness, prognosis, available treatments, legal decisions, and quality-of-life issues. Education, including short- and long-term programs, improves caregiver knowledge and confidence, and in some cases, delays time to nursing home placement.[39] Table 63–3 lists basic principles of care for the AD patient. Communication between the patient and family members is essential in order to minimize stress on everyone.

The general approach to developing nonmedication strategies for behavioral symptoms is to identify the symptom, identify causative factors, and adapt the caregiving environment to remedy the situation.[4] Environmental triggers may include noise, glare, an insecure space, and too much background distraction, including television. Personal discomfort may also trigger behaviors, so it is important to monitor for pain, hunger, thirst, constipation, full bladder, fatigue, infections and skin irritation, comfortable temperature, fears, and frustrations.[4] Medical comorbidity is a major source of functional and cognitive impairment in patients with AD, so general health maintenance is warranted.[44] Interventions should redirect the patient's attention rather than be confrontational and should specifically address known triggers. Creating a calm environment and removing stressors and triggers is key. Caregivers should be referred to support services, such as the Alzheimer's Association, for assistance in developing nonpharmacologic strategies for managing difficult behaviors.

The caregiver must be prepared to face the changes in life that will occur, and acceptance of this does not come easily. Denial on the part of the patient and rationalization on the part of the family are common. The clinician should encourage the family to address legal and financial matters and designate a durable power of attorney for execution of financial and medical decisions once the patient is incompetent. The caregiver will need to address issues such as respite services to provide time for rest, relaxation, and conduct of personal business. Caregiver stress impacts the health and quality of life of the caregiver as well as the patient. Eventually, the caregiver will need to face critical questions with respect to institutionalization. This is probably the most difficult decision for the caregiver. Clinician support and referral to social services is vitally important in assisting the caregiver at that moment. The family should also be referred to local resources, such as the Alzheimer's Association, that can provide detailed information regarding support services. Table 63–4 lists some referral sources for caregivers.

Education, communication, and planning are the key nonpharmacologic components of caring for an AD patient. Preparation in the early stages of illness will lessen some of the caregiver stress as the illness progresses.

TABLE 63-3 Basic Principles of Care for the Alzheimer's Patient

- Consider vision, hearing, or other sensory impairments.
- Find optimal level of autonomy and adjust expectations for patient performance over time.
- Avoid confrontation. Remain calm, firm, and supportive if the patient becomes upset.
- Maintain a consistent, structured environment with stimulation level appropriate to the individual patient.
- Provide frequent reminders, explanations, and orientation cues. Employ guiding, demonstration, and reinforcement.
- Reduce choices, keep requests and demands of the patient simple, and avoid complex tasks that lead to frustration.
- Bring sudden declines in function and the emergence of new symptoms to professional attention.

Data from Alzheimer's Association,[4] Rubin,[47] and Lyketsos et al.[57]

PHARMACOLOGIC THERAPY

Pharmacotherapy for Cognitive Symptoms

8 Table 63–5 presents a treatment algorithm for managing cognitive symptoms in AD. Cholinesterase inhibitors and NMDA-receptor

TABLE 63-5 Treatment Options for Cognitive Symptoms in Alzheimer's Disease

- In mild to moderate disease, consider therapy with a cholinesterase inhibitor:
  - Donepezil or
  - Rivastigmine or
  - Galantamine
- Titrate to recommended maintenance dose as tolerated.
- In moderate to severe disease, consider adding antiglutamatergic therapy:
  - Memantine
- Titrate to recommended maintenance dose as tolerated.
- Alternatively, consider memantine or cholinesterase inhibitor therapy alone.
- Behavioral symptoms may require additional pharmacologic approaches.

Data from Burns and Iliffe,[1] Lleó et al.,[44] and Lyketsos et al.[57]

antagonists are indicated for treatment of AD. The latest treatment guideline recommends the use of cholinesterase inhibitors for AD, with no preference for a specific agent.[40–42] Donepezil, rivastigmine, and galantamine are indicated in mild to moderate AD, while donepezil is also indicated in severe disease. Memantine is indicated for moderate to severe AD; current evidence does not support its use in earlier stages of the disease.[43] Additional benefit may be achieved when memantine is added to cholinesterase inhibitor therapy in moderate to severe AD.[44,70] There is no evidence supporting combination therapy of more than one cholinesterase inhibitor.

Disagreement exists about how to determine effectiveness of treatments for AD. Selection of qualitative versus quantitative assessment may bias a clinician's impression of response. Subtle changes are often detected only by psychometric testing rather than with routine questioning. Because no standard has been suggested to define the effectiveness of these medications, great variation exists between clinicians and the duration of treatment ranges from months to years. Realistic expectations for treatment success may include short-term improvement of symptoms and less decline in behavioral, functional, and cognitive abilities over the longer term.[36]

Unfortunately, clinical trials have failed to provide answers to key questions in treating AD patients. Information from clinical trials is insufficient to know if a cholinesterase inhibitor dose—response relationship exists, or if additional cognitive improvement may be gained by increasing to the maximum tolerated dose, rather than continuing with the usual recommended daily dosage. Guidance in extrapolating data related to changes in cognition is needed so that a reasonable duration of clinical treatment with cholinesterase inhibitors and NMDA-antagonists can be determined.

In natural disease progression studies, scores on the Alzheimer's Disease Assessment Scale—Cognition (ADAS-cog) have been shown to worsen (increase) by an average of 4 points over 6 months and 7 points over 1 year. Based on these findings, the general consensus is that a 4-point change in the ADAS-cog represents a clinically significant change. Therefore, if a pharmacotherapeutic agent decreases the ADAS-cog by 4 points, one could think of this as having reversed progression of disease symptoms by 6 months. The usefulness of the ADAS-cog in clinical practice is limited because of the time required for administration; it is much more practical to assess changes in disease severity using the Mini-Mental Status Examination (MMSE). An untreated patient has an average decline of 2 to 4 points in MMSE score per year. Consequently, successful treatment would reflect a decline of less than 2 points a year. It is reasonable to change to a different cholinesterase inhibitor if the decline in MMSE score is greater than 2 to 4 points after 1 year with the initial agent.

8 Cholinesterase Inhibitors In the early 1980s, researchers began to examine means to enhance cholinergic activity in patients with AD by inhibiting the hydrolysis of acetylcholine through reversible inhibition of cholinesterase. Tacrine was the first such drug to be examined in a systematic fashion. However, tacrine is fraught with significant side effects, including hepatotoxicity, that severely limit its usefulness. For all practical purposes the use of tacrine has been replaced by the use of safer, more tolerable cholinesterase inhibitors. The newer cholinesterase inhibitors donepezil, rivastigmine, and galantamine show similar efficacy and adverse event profiles to one another and are generally well tolerated. The most frequent adverse events associated with these agents are mild to moderate gastrointestinal symptoms (nausea, vomiting, and diarrhea).[44] Other cholinergic side effects are generally dose related and include urinary incontinence, dizziness, headache, syncope, bradycardia, muscle weakness, salivation, and sweating. Gradual dose titration over several months can improve tolerability.[42] Abrupt discontinuation can lead to worsening cognition and behavior in some patients.[45,46] Concurrent use of anticholinergic medications with cholinesterase inhibitors should be avoided.

Table 63–6 summarizes the clinical pharmacology of the cholinesterase inhibitors. The mechanism of action differs slightly between drugs in this class.[47] Donepezil specifically and reversibly inhibits acetylcholinesterase. Rivastigmine inhibits both butyrylcholinesterase and acetylcholinesterase. Galantamine is a selective, competitive, reversible acetylcholinesterase inhibitor and also enhances the action of acetylcholine on nicotinic receptors. The clinical relevance of these differences is unknown. Choice of cholinesterase inhibitor therapy for an individual patient is based on ease of use, patient preference, cost, and safety issues such as potential for drug interactions.[40,41] In 2008, galantamine became available in generic form, which has reduced the cost of galantamine therapy. A generic form of donepezil has also been approved by the U.S. Food and Drug Administration (FDA) in December 2009, and (as of this writing) may become available as early as 2010.

TABLE 63-6 Clinical Pharmacology of Cognitive Enhancing Medications

	Donepezil	Rivastigmine	Galantamine	Memantine
Brand Name	Aricept	Exelon	Razadyne	Namenda
Dosage Forms	Tablet Orally disintegrating tablet	Capsule Oral solution Patch	Tablet Oral solution Extended-release (ER) capsule	Tablet Oral solution (Extended-release formulation in development)
Starting Dose	5 mg daily in the evening	1.5 mg twice a day 4.6 mg/day (patch)	4 mg twice a day 8 mg daily for (ER)	5 mg once daily
Maintenance Dose	5–10 mg daily 23 mg daily in moderate to severe AD	3–6 mg twice a day 9.5 mg/day (patch)	8–12 mg twice a day (16–24 mg daily for ER)	10 mg twice a day
Meals	Can be taken with or without food	Take with meals	Take with meals	Can be taken with or without food
Mechanism of Action	Reversible inhibition of acetylcholinesterase	Reversible inhibition of acetylcholinesterase and butyrylcholinesterase	Reversible inhibition of acetylcholinesterase and modulation of nicotinic receptors	Antagonism of *N*-methyl-D-aspartate (NMDA) receptors
Half-Life	70 hours	1.5 hours	7 hours	60–80 hours
Protein Binding	96%	40%	18%	45%
Metabolism	Substrate (minor) of CYP2D6 and 3A34; glucuronidation	Cholinesterase-mediated hydrolysis	Substrate (minor) of CYP2D6 and 3A34; glucuronidation	Glucuronidation
Renal Elimination	Yes	Major pathway	Yes	Yes

Data from references 48 and 92–95.

CLINICAL CONTROVERSY

Several cholinesterase inhibitors are now available, raising the question of whether it is appropriate to switch a patient from one to another if the first is not considered effective. Theoretical differences exist in their mechanisms of action, but many clinicians feel that these differences are not clinically meaningful, and therefore that switching is not helpful. Switching is recommended if a patient is not tolerating the initial treatment. Most clinicians probably do switch to another agent, and initial data seem to indicate that some patients do respond to an alternative cholinesterase inhibitor. Usually switching is performed without a washout period and interruptions for longer than 3 weeks are not advised.[44]

8 Antiglutamatergic Therapy Memantine is the only NMDA-antagonist currently available. At concentrations achieved at least under in vitro conditions, memantine blocks glutamatergic neurotransmission by antagonizing NMDA receptors. Glutamate is an excitatory neurotransmitter in the brain implicated in long-term potentiation, a neuronal mechanism important for learning and memory.[44] Under experimental conditions, blocking NMDA receptors can mitigate excitotoxic neurotoxicity and provide neuroprotection. There is currently no evidence to indicate memantine confers neuroprotection in AD.[43,44]

Memantine has been studied in patients with moderate and severe AD as monotherapy and in combination with donepezil with modest favorable results on cognition and function.[43] It is currently indicated for use in AD patients with moderate to severe illness. Studies of memantine alone and in combination with cholinesterase inhibitors in mild AD performed to date have provided insufficient evidence to support an indication for mild AD.[4]

Memantine has 100% bioavailability regardless of administration with or without food. Protein binding is low. Memantine is not metabolized by the liver and does not inhibit cytochrome P450. Memantine is primarily excreted unchanged in the urine. The half-life ranges from 60 to 80 hours.[44]

Overall, memantine has been well tolerated in clinical trials. The most common adverse events associated with memantine include constipation, confusion, dizziness, headache, hallucinations, coughing, and hypertension.[48]

Memantine is likely to be used as monotherapy and also in combination with cholinesterase inhibitors in patients with moderate to severe AD. Memantine should be initiated at 5 mg once a day and increased weekly by 5 mg a day to the effective dose of 10 mg twice daily.[48] It may be given with or without food. Dosing of 10 mg daily is recommended in patients with severe renal impairment (creatinine clearance of 5–29 mL/min [0.08 to 0.49 ml/s]).[48]

Role of Combination Therapy Combination therapy with memantine added to cholinesterase inhibitor therapy is generally prescribed for patients with moderate to severe AD. The rationale for this add-on therapy is that the drug classes have different mechanisms of action. The clinical effectiveness of using combination therapy with a cholinesterase inhibitor plus memantine was compared to using a cholinesterase inhibitor alone and no treatment.[49] This study showed significant decreases in the rate of progression of dementia across the treatment groups, such that patients who received combination therapy showed the least decline in cognitive function, followed by the group that only received cholinesterase inhibitors. The group that received combination also had the lowest rate of decline in functional status. Another combination trial assessed the efficacy and safety of memantine versus placebo in patients with moderate to severe AD already receiving stable treatment with donepezil.[50] Patients randomized to combination therapy with memantine and donepezil showed significant improvements in cognition and function in this 6-month study. However, in patients with mild to moderate AD, there were no benefits seen when memantine therapy was added to a cholinesterase inhibitor.

Available data suggest treatment strategies currently under investigation will at best slow rather than arrest cognitive decline.[52] It therefore seems reasonable to predict that for the foreseeable future combination therapy will become increasingly common in AD, especially as drugs or treatments with unique mechanisms of action become available, and drugs with neuroprotective modes of action are concomitantly used with symptomatic drugs.

Effect of Current Treatments on Neurodegenerative Processes AD is a progressive disorder. Affected individuals typically experience some degree of cognitive decline and histologic change years (if not decades) before a diagnosis is made. Therefore, the ideal treatment will be one that not only reverses symptoms by enhancing cognitive function (a symptomatic treatment), but also arrests the neurodegeneration-relevant molecular processes that underlie cognitive decline (a disease-modifying treatment).

Clinical trials for AD prompt consideration of whether positive outcomes suggest either a symptomatic or disease-modifying effect. Any rapid performance improvement on cognitive ability, activities of daily living, or behavioral end points is indicative of a symptomatic effect. All cholinesterase inhibitor agents and memantine demonstrate this pattern. On the other hand, arrest of decline or a sustained reduction in the slope of decline would argue the presence of a disease-modifying effect. It has not been possible to unequivocally demonstrate this in trials of the currently approved treatments. Definitive trials evaluating whether cholinesterase inhibitors or memantine have disease-modifying effects are difficult to perform, because doing so requires continuing a placebo arm over an extended period, well beyond demonstration of symptomatic benefit. Also, subject attrition over an extended study would complicate both intent-to-treat and observed cases analyses.

With the currently approved AD drug treatments, placebo-controlled pivotal trials were followed by open-label extension studies. Published studies have lasted as long as 5 years, and as part of these studies, decline in the treatment group was compared with "projected" placebo groups based on the placebo groups followed during the 6-month randomized phase of the efficacy study, as well as natural history cohorts from the pre-cholinesterase inhibitor therapy era. Although analyses of this sort conclude that, for up to at least 5 years, persons receiving treatment exceed their projected nontreatment cognitive performance, no convincing evidence of a disease-modifying effect emerges.[53–56]

CLINICAL CONTROVERSY

Disagreement exists about the usefulness of current therapies for AD in advanced stages of the disease. Some clinicians believe that patients should be taken off cognitive-enhancing medications once they have reached very severe stages of AD, whereas others believe that these medications may continue to be helpful with managing psychiatric symptoms and maintaining function. Many clinicians discontinue cognitive-enhancing medications once the AD patient is bedridden and unable to perform activities of daily living.

Management of Brain Vascular Health

9 Guidelines for the principles of care of patients with AD support the management of vascular brain disease and its associated risk factors as part of the treatment of AD.[57] There is a growing body of evidence that brain vascular disease plays an important role in the progression of dementia. For a given level of Alzheimer's pathology, vascular disease in the brain may add to the degree of cognitive impairment.[57] Management of brain vascular disease includes monitoring blood pressure, glucose, cholesterol, and homocysteine and initiation of appropriate interventions.[57] Guidelines recommend initiation of low-dose aspirin therapy in patients with AD with significant brain vascular disease.[57] Elevated homocysteine levels correlate with decreased performance on cognitive tests, but there remains insufficient evidence of a benefit of B vitamin supplementation (B_6, B_{12}, and folic acid) on cognitive function in patients with AD.[58] Reducing the risk for developing brain vascular disease may also be an important strategy in reducing the risk for developing AD. The Alzheimer's Association's Maintain Your Brain campaign is designed to increase awareness of the importance of brain health as a part of healthy aging and recommends staying physically, mentally, and socially active; adopting a low-fat, low-cholesterol diet rich in dark vegetables and fruit; and managing body weight, blood pressure, cholesterol, and blood sugar to reduce the risk of heart disease, stroke, and diabetes.[4] Appropriate management of vascular disease risk factors may reduce the risk for developing AD.[59]

Other Potential Treatment Approaches

Estrogen Estrogen replacement has been studied extensively for the treatment and prevention for AD. Most, but not all, retrospective epidemiologic studies show a lower incidence of AD in women who took estrogen replacement therapy postmenopausally.

Prospective clinical trials have not supported the use of estrogen as a treatment for cognitive decline and longer trials tend to suggest harm. Overall, the evidence does not support the use of estrogen to treat or prevent dementia.[41,60]

Antiinflammatory Agents Retrospective epidemiologic studies suggest a protective effect against AD in patients who have taken NSAIDs. The benefits of antiinflammatory agents have been less compelling in prospective clinical studies. NSAIDs have had no cognitive benefit in AD patients or else benefits so minimal the risk of harm exceeds the potential benefit.[61–63] Tolerability is problematic.[61–64] Additionally, prednisone treatment was associated with worsening behavioral symptoms.[64] Because there is a lack of compelling data and also a significant incidence of adverse effects, particularly gastritis and the possibility of gastrointestinal bleeds, NSAIDs and prednisone are not recommended for general use in the treatment or prevention of AD at the present time.

Lipid-Lowering Agents A potential AD protective effect has been postulated for lipid-lowering agents, particularly the 3-hydroxy-3-methylglutaryl-coenzyme A-reductase inhibitors. Longitudinal epidemiologic studies suggest an association between elevated midlife total cholesterol levels and AD.[21] Increased risk of dementia does not appear to be associated with hypercholesterolemia in late life however.[21] Other studies note that the incidence of AD is lower in patients who have taken either a statin or another lipid-lowering agent, but not in patients who were taking other cardiovascular medications.[21] It is important to note that not all epidemiologic studies suggest an association between cholesterol and AD.[21]

Randomized controlled trials of statin therapy given in late life to patients at risk for vascular disease indicate that statins do not prevent AD.[65] Several randomized controlled trials of statins for the treatment of mild to moderate AD have been completed or are ongoing. Thus far, these trials have not demonstrated a significant benefit of statin therapy, but results of ongoing trials should help to clarify the role of statins in the treatment of AD.[66] Interestingly, cognitive impairment has been recognized as a rare adverse event associated with statin therapy. The extent of cognitive impairment may depend on the lipid solubility of the drug, regulating the amount of drug that is able to cross the blood—brain barrier. As simvastatin and lovastatin have the highest lipophilicity, they may be the most likely candidates to cause memory impairment.[67] More research is needed to understand the complex relationship between cholesterol, statin therapy, and cognitive functioning. For now these agents should be reserved for patients who have other indications for their use.[57]

Dietary Supplements

Vitamin E Based on pathophysiologic theories involving oxidative stress and the accumulation of free radicals in AD, significant interest has evolved regarding the use of antioxidants in the treatment of AD. For a period starting in the late 1990s, vitamin E was frequently recommended as adjunctive treatment for AD patients. This was based on data from the only published clinical trial to date, which evaluated the time to critical end points (i.e., death, institutionalization, loss of ability to perform activities of daily living, or severe dementia) in patients treated with vitamin E, selegiline, the combination, or placebo.[68] Although vitamin E and selegiline were superior to placebo, this study has been criticized because of differences in baseline cognitive severity, calling the validity of the results into question. Because of vitamin E's perceived safety (at that time) and low cost, doses of up to 2,000 IU per day were commonly recommended.

Evidence related to vitamin E's role in prevention of AD is mixed. Epidemiologic studies in individuals without AD have yielded conflicting results, with some studies showing delay in the onset of AD in individuals taking vitamin E supplements, but others failing to find this association.[44] Some studies have also found that dietary intake of vitamin E is associated with reduced risk, while others have not.[44] A study in patients with mild cognitive impairment failed to show that vitamin E had a significant effect on slowing the progression to AD.[68]

Vitamin E treatment may also be associated with risks. Side effects observed with vitamin E administration include impaired hemostasis, fatigue, nausea, diarrhea, abdominal pain, and falls.[68] A meta-analysis found that high-dose vitamin E increases mortality in supplemented subjects.[69] In light of these findings, vitamin E supplementation is not recommended for the treatment of AD.[41]

Nutraceuticals, Supplements, and Medical Foods *Ginkgo biloba* for the prevention and treatment of AD has been extensively studied. Rationales for studying Ginkgo for AD have included its potential to increase blood flow, decrease blood viscosity, antagonize platelet-activating factor receptors, increase anoxia tolerance, inhibit monoamine oxidase, and serve as an antioxidant. Active ingredients in *G biloba* include flavonoids, the Ginkgoflavone glycosides, and bioflavonoids. Most studies reporting benefit in patients with AD have studied a standardized extract, EGb 761, in doses of 120 mg per day for at least 4 to 6 weeks. Those advocating the use of Ginkgo for AD suggest doses of 120 to 240 mg of the standard leaf extract twice per day be used, and note 12 weeks of consistent dosing may be needed to observe an effect.[70] However, a large trial of *G biloba* in which the 120 mg twice a day dose was studied did not reduce either the overall incidence rate of dementia or AD incidence in elderly individuals with normal cognition or MCI.[71] Side effects reported from EGb 761 studies were typically mild but did include nausea, vomiting, diarrhea, headaches, dizziness, palpitations, restlessness, and weakness. Because EGb also has a potent antiplatelet effect, it should be avoided by individuals

taking anticoagulant or antiplatelet therapies, and should be used cautiously in patients taking NSAIDs.[70,72] Further, the content of retail herbal products is poorly standardized, and significant variation in purported active ingredient content can exist from lot to lot and between manufacturers. Current practice guidelines do not recommend Ginkgo for the prevention or treatment of AD.[57]

Huperzine A is an alkaloid isolated from the Chinese club moss, *Huperzia serrata*. It reversibly inhibits acetylcholinesterase and is administered orally in doses of 50 to 200 mcg 2 to 4 times daily. Nondefinitive clinical studies suggest huperzine A may have efficacy in the symptomatic treatment of AD, but more studies are needed to determine its place in therapy. In a medium-sized, randomized, double-blind, placebo-controlled multicenter study in patients with mild to moderate AD performed in China, treatment with huperzine A at doses of 400 mcg/day for 12 weeks resulted in improvement in cognition by an average of 4.6 points assessed by ADAS-cog (P = 0.000), 2.7 points on the MMSE, and 1.5 points on the Alzheimer's Disease Assessment Scale—noncognition (P = 0.008).[73] Replication of these study results are still pending. The current consensus is that huperzine A has not been adequately studied for use in AD, its consistency in retail products remains a concern, and potential side effects could be substantial, especially in those taking cholinesterase inhibitors.[70,74] Huperzine A is not currently recommended for AD treatment.

Arguments that omega-3 fatty acids found in fish oil, such as docosahexaenoic acid, could benefit AD subjects have existed for some years. A large prospective, placebo-controlled trial of docosahexaenoic acid in AD subjects was recently reported. For the most part, results were disappointing, and although it could not be ruled out that population subsets did benefit, the primary study end points were negative.[75] At the time of this chapters' preparation, testing of other dietary supplements, such as curcumin, is ongoing.[70]

Currently, the only dietary agent approved by the FDA for the treatment of AD is AC1202, which is sold under the commercial name Axona. AC1202 is a modification of medium-chain triglyceride formulations used decades ago for the treatment of pediatric epilepsy; such formulations contain mixtures of C5–C12 fatty acids. AC1202 consists primarily of the C8 fatty acid, caprylic acid. AC1202 is converted by the liver to a ketone body, betahydroxybutyrate, which is secreted into the blood stream. Betahydroxybutyrate crosses the blood—brain barrier and can be used as an oxidative phosphorylation substrate by neuron mitochondria. Due to its ability to support brain bioenergetics, which is impaired in AD, betahydroxybutyrate was first proposed as a potential AD treatment in 1989.[76] Support for AC1202 efficacy in the treatment of AD comes mostly from a phase IIb trial in which subjects randomized to 40 mg per day of AC1202 for 45 days performed relatively better on the cognitive portion of ADAS-cog than did subjects randomized to a placebo.[77] A subanalysis of these data revealed this benefit was entirely driven by subjects who did not have an *APOE*4* allele. For *APOE*4* carriers, ADAS-cog performance between subjects receiving AC1202 and placebo were comparable at all time points studied. Gastrointestinal-related side effects were common but in general side effects were felt to be mild. Based on these data and on the established safety track record of medium-chain triglyceride oil, in 2009 the FDA gave permission for AC1202 to be marketed as a medical food for the treatment of AD. Medical foods constitute a unique category that consists of ingestible entities specifically intended for the treatment of diseases that have "specific nutritional requirements" and in which the medical food may manipulate disease-relevant pathophysiology. Although medical foods regulatory approval standards are not nearly as rigorous as those required for approvals of new medications, medical foods are not available over-the-counter and are obtained only by prescription.

CLINICAL CONTROVERSY

The compound tramiprosate (homotaurine), or Alzhemed, showed promise as a treatment of Alzheimer's disease in early development. In animal studies, homotaurine demonstrated the ability to interfere with the actions of Aβ early in the amyloid cascade, subsequently preventing amyloid plaque formation and subsequent degeneration of neuronal cells. Phase III trials were disappointing, and the FDA refused to approve marketing of homotaurine as a prescription drug. Homotaurine is naturally occurring in seaweed, and its manufacturer decided to remarket the product as the dietary supplement, Vivimind for age-associated memory impairment. Controversy exists between those who advocate for availability of dietary supplements to consumers and those who advocate for evidence-based medicine. The major concern is the marketing of potentially ineffective products to those suffering from memory loss or dementia.[96]

Drugs and Treatment Strategies in Development

Current drug development strategies fall broadly into one of two categories. The first category includes treatments specifically designed to reduce levels of brain Aβ or manipulate its configuration. The second category includes all other strategies.

To reduce brain amyloid levels, approaches to both reducing Aβ production and enhancing its removal have been and still are undergoing evaluation. Aβ is produced through enzymatic processing of APP by two enzyme complexes, the β- and γ-secretases. β-Secretase inhibitors have entered phase II human trials. Agents that specifically inhibit γ-secretase could prove problematic from a side-effect perspective, as γ-secretase is also critical for processing Notch3, a protein of developmental importance and perhaps brain maintenance. Certain NSAIDs (ibuprofen and flurbiprofen) influence the γ-secretase but do not inhibit it outright. In general, these NSAIDs alter where γ-secretase cuts the APP protein. An enantiomer of flurbiprofen, tarenflurbil, recently completed a large phase III efficacy trial in which no evidence of efficacy was seen.[52]

Immunotherapy approaches have been studied as a way to enhance Aβ removal. The most extensive investigation involved AN1792, a Aβ-based vaccine. A phase II trial in humans was prematurely halted after a substantial percentage of those mounting a robust immune response to the vaccine experienced encephalitis, a potentially life-threatening brain inflammation. The most comprehensive, long-term clinicopathologic study of subjects receiving AN1792 later concluded vaccinated subjects show a predictable rate of cognitive decline and that despite reducing brain plaque burdens, AN1792 vaccination is unlikely to meaningfully benefit those with the common form of late-onset, sporadic AD.[78]

Most proponents of the amyloid cascade hypothesis currently claim the species of Aβ that is most likely to prove relevant to AD neurodegeneration are Aβ oligomers. Aβ oligomers are formed through limited aggregation of Aβ monomers. Aβ oligomers are too small to form fibrils and may retain aqueous solubility. A drug called tramiprosate was previously created to prevent Aβ oligomer formation and tested clinically in a large phase III trial. No evidence of efficacy was seen.[52]

Despite these failures, the next generation of amyloid clearance therapies are currently under development. This generation includes modifications of the active immunization approach that, hopefully, will not trigger encephalitis. Passive immunization approaches via antibody infusions are also under investigation. At the time of this writing, results of a phase III trial of bapineuzumab, an Aβ antibody, are expected in 2010. The usefulness of treating

AD subjects with intravenous immunoglobulin preparations, which naturally contain antibodies to Aβ, is under evaluation.[52]

The second category of AD treatment development includes efforts not specifically intended to reduce brain Aβ levels. Neuroscientists are unraveling intracellular pathways involved in cell information processing, and drugs that can modulate these pathways are under development. Drugs that retard neurofibrillary tangle formation in mice expressing mutant human *tau* transgenes, such as valproic acid, were recently tested in humans, although no evidence of efficacy was seen. Other "anti-tangle" drugs are in various stages of development.[52] The thiazolidinedione drugs rosiglitazone and pioglitazone, which reduce insulin resistance and which may also have antiinflammatory effects, were recently tested in humans with AD, although the most definitive of these trials showed no evidence of efficacy. Despite this, efforts at treating AD through modification of insulin signaling pathways are ongoing.[52]

A phase II trial of latrepirdine (dimebon) recently generated much attention.[79] Suggestions of efficacy in phase II trials in no way ensures efficacy will be seen in phase III trials. This caveat seems especially pertinent in AD drug development, as phase II trials of flurbiprofen, tramiprosate, and rosiglitazone all reported some evidence of efficacy that did not bear out in phase III studies. However, in the initial 6-month placebo-controlled trial, which was conducted in Russia, AD subjects randomized to dimebon performed better on cognitive and overall performance measures than those randomized to placebo. Subjects subsequently enrolled in a 6-month open-label continuation study continued to perform above their pre-study baseline. This was the first study in which AD subjects have been reported to perform above their pre-treatment baseline over the course of a full year. At concentrations achieved in human subjects dimebon does not appear to act as a cholinesterase inhibitor or NMDA-receptor antagonist. It does not appear to reduce Aβ production and indeed in animal models appears to increase Aβ production. There are data that suggest nanomolar concentrations of dimebon affect mitochondrial function. Unfortunately, results from a phase III Dimebon study reported in Spring 2010 failed to show efficacy in the treatment of AD.

Obviously, successful development of new AD treatments depends on elucidating AD's true underlying pathophysiology. If AD is a primary amyloidosis, as is postulated by the amyloid cascade hypothesis, then reducing Aβ would seem a rational way to proceed with drug development. If AD is not a primary amyloidosis, then the impact antiamyloid therapies have on the disease will be limited at best. Finally, at genetic and epidemiologic levels, it is now possible to define several different Alzheimer's "diseases." It is not unreasonable to consider whether treatments useful in one type of AD may not benefit patients with another type.

PHARMACOTHERAPY OF NONCOGNITIVE SYMPTOMS

The majority of patients with AD manifest noncognitive symptoms at some point in the illness.[37] These symptoms can be roughly divided into three categories: psychotic symptoms, inappropriate or disruptive behavior, and depression. Effective management of these problems is important because behavioral symptoms are distressing to both the patient and the caregiver, necessitate increased caregiver supervision and patience, and are a leading reason for nursing home placement. In fact, presence of neuropsychiatric symptoms increases caregiver burden more than loss of cognition or self-care.

10 Strategies for treatment of psychotic or behavioral symptoms should include environmental interventions first, then pharmacologic interventions if warranted. The need for medications may exist when neuropsychiatric symptoms are of sufficient severity to cause significant distress to the patient or caregiver, interfere with function or cause disability, impede delivery of necessary care, or pose a danger to self or others.[41,57] The balance between risks of the medication and expected benefits must be acceptable to the patient or surrogate decision maker. Medications should be used cautiously, with adequate monitoring for efficacy and adverse events.

Despite the high prevalence of noncognitive symptoms in AD, little research has been conducted in these patients. Data from clinical trials of antidepressants, cholinesterase inhibitors, and antipsychotics are now emerging, but clearly more research is needed. Because of limited clinical data, treatment is primarily empiric, with side-effect profiles used as a guide in selecting the appropriate treatment. Psychotropic medications with anticholinergic effects should be avoided because they may actually worsen cognition and interfere with cholinesterase inhibitor therapy. Other side effects in the elderly include sedation, medication-induced postural instability, and extrapyramidal side effects, which can decrease the clinical usefulness of traditional psychotropic agents.

General guidelines governing therapy can be summarized as follows: use reduced doses, monitor closely, titrate dosage slowly, and document carefully. Caregivers often have erroneous expectations regarding the effects of psychotropic medications, and the anticipated benefits and risks of therapy should be clearly explained. Disruptive behaviors and delusions wax and wane with disease progression. Attempts to slowly taper and discontinue antipsychotic medication should be undertaken regularly in minimally symptomatic patients, because some patients improve on medication withdrawal.[57] Table 63–7 outlines suggested doses of medications.

Cholinesterase Inhibitors and Memantine

Clinical trials with cholinesterase inhibitors have consistently reported modest benefit in managing neuropsychiatric symptoms, although these are generally not the primary outcomes studied in the trials.[80–82] Any benefits in symptoms such as agitation may accrue gradually over time, since cholinesterase inhibitors may not significantly reduce agitation when administered to patients experiencing acute agitation.[83] Memantine shows modest behavioral benefits as well, either alone or in combination with cholinesterase

TABLE 63-7 Medications Used for Noncognitive Symptoms of Dementia

Drugs	Starting Dose (mg)	Maintenance Dose in Dementia (mg/d)	Target Symptoms
Antipsychotics			Psychosis: hallucinations, delusions, suspiciousness Disruptive behaviors: agitation, aggression
Haloperidol	0.25	1–3	
Olanzapine	2.5	5–10	
Quetiapine	25	100–300	
Risperidone	0.25	0.75–2	
Ziprasidone	20	40–160	
Antidepressants			Depression: poor appetite, insomnia, hopelessness, anhedonia, withdrawal, suicidal thoughts, agitation, anxiety
Citalopram	10	10–20	
Escitalopram	5	20–40	
Fluoxetine	5	10–40	
Paroxetine	10	10–40	
Sertraline	25	75–100	
Venlafaxine	25	75–225	
Trazodone	25	75–150	
Anticonvulsants			Agitation or aggression
Carbamazepine	100	200–600	
Valproic Acid	125	500–1,000	

Data from Lleó et al.,[44] Benoit et al.,[37] and Grossberg and Desai.[97]

inhibitors, and may also spare the use of antipsychotics to treat agitation.[80,81] These treatments can provide modest short-term improvement and possibly slow the development and progression of behavioral symptoms. Cholinesterase inhibitors also have a small beneficial effect on caregiver burden and active time use among caregivers of persons with AD.[84] These benefits should be considered along with cognitive benefits in treatment decisions. Long-term effects on behavior have not been demonstrated to date, and further research is needed.

Antipsychotics

Antipsychotics are widely used in the management of neuropsychiatric symptoms in AD. There is modestly convincing evidence that most of the atypical antipsychotics provide some benefit for particular neuropsychiatric symptoms, but these data have been insufficient to gain FDA approval as an indication for the management of behavioral symptoms in AD. Based on a recent meta-analysis, only 17% to 18% of dementia patients show a treatment response to atypical antipsychotics.[85] In a double-blind, placebo-controlled trial of 421 outpatients with AD and psychosis, aggression, or agitation randomized to receive olanzapine, quetiapine, risperidone, or placebo for up to 36 weeks, there were no significant differences among the treatments in time to discontinuation of treatment or improvement in the Clinical Global Impression of Change scale. The investigators concluded that adverse effects offset advantages in the efficacy of atypical antipsychotic drugs for treatment of psychosis, aggression, or agitation in patients with AD.[85] Adverse events are common with atypical and typical antipsychotics in patients with AD. These adverse events associated with atypical antipsychotics include somnolence, extrapyramidal symptoms, abnormal gait, worsening cognition, cerebrovascular events, and increased risk of death.[86] Typical antipsychotics may also be associated with a small increased risk of death, as well as more severe extrapyramidal effects and hypotension. Chapter 76 has a more detailed discussion of antipsychotic adverse events. Overall, there is a modest expectation of treatment benefit and potential for significant harm associated with antipsychotic use in patients with AD. Individual risk and benefit must be considered when initiating therapy. Diligent monitoring during treatment is essential along with frequent reassessment of continued need.

CLINICAL CONTROVERSY

Antipsychotic medications have been widely used to treat disruptive behaviors and psychosis in AD patients, although the evidence supporting their modest benefit for some symptoms is limited.[86] Use of antipsychotics to treat severe neuropsychiatric symptoms in AD remains controversial. Recent studies indicate that atypical and typical antipsychotics have been associated with infrequent but serious adverse events, including a small increased risk of death.[81,85] These findings resulted in a FDA-mandated "black box warning" concerning the use of atypical antipsychotics in the treatment of AD. Careful consideration of risk versus benefit in individual patients is warranted.

Antidepressants

Depressive symptoms are common in patients with AD, occurring in as many as 50% of patients.[44] Apathy may be even more frequent, but these symptoms may be difficult to distinguish in patients with dementia. Many trials have studied the efficacy of antidepressants in treating depression in patients with AD, but the results are conflicting. Small sample size, short duration of treatment, and differing measures of therapy outcomes limit comparison across studies and may account in part for conflicting study results.[44] Improvement in patients receiving placebo is also common. In practice, treatment with selective serotonin reuptake inhibitors (SSRIs) is initiated most commonly in patients with AD, based on side-effect profile and evidence of efficacy.[41] Among the SSRIs, the best evidence exists for sertraline and citalopram.[81] Buproprion, venlafaxine, and mirtazapine may be alternatives.[41] Serotonergic function may also play a role in some of the other behavioral symptoms of AD, and some studies support the use of SSRIs in the management of these behaviors, even in the absence of depression.[81] Tricyclic antidepressants have efficacy similar to the SSRIs, but should generally be avoided because of their anticholinergic activity.[41] There is little evidence for the use of trazodone to manage behavioral or depressive symptoms, but it is commonly recommended to treat insomnia in patients with AD.[41]

Chapter 77 has a more complete discussion of treatment of depression.

Miscellaneous Therapies

Because antipsychotic and antidepressant therapy has shown only modest efficacy and poses a risk of undesirable side effects, medications traditionally used to treat disruptive behaviors and aggression in other psychiatric and neurologic disorders have been suggested as potential alternatives. These alternatives include benzodiazepines, buspirone, and antiepileptics.[81]

Benzodiazepines have been used to treat anxiety, agitation, and aggression, but the benefit is generally modest.[41] Because benzodiazepines impair cognition, worsen breathing disorders, and may increase the risk of falls in AD patients, their routine use is not advised, except on an "as needed basis" for infrequent episodes of agitation.[41] "Mood stabilizer" anticonvulsants such as carbamazepine, valproic acid, or gabapentin may be appropriate alternatives, but evidence is conflicting.[81] Clearly, more rigorous placebo-controlled studies are needed to determine the relative efficacy and place in therapy for these medication alternatives.

Noncognitive symptoms are often the most difficult aspect of AD for the caregiver. When nonpharmacologic approaches fail, selected antipsychotics and antidepressants have been useful for effective management of behavioral, psychotic, and depressive symptoms, thereby easing caregiver burden and allowing the patient to spend additional time at home. Alternative treatments are available in case initial choices are not successful. Adverse events remain an important concern in this population.

PHARMACOECONOMIC CONSIDERATIONS

The economic and social costs of AD are staggering. It is the third most expensive illness in the United States after heart disease and cancer, and the majority of medical and caregiving expenses are left to the patients' families and to government programs (state and federal). The total national cost of AD is estimated at approximately $148 billion annually.[4] In 2005, annual Medicare costs were estimated at $91 billion and Medicaid costs for institutionalized AD patients were estimated at $21 billion.[4] With life expectancy and the number of AD cases increasing, the cost of AD is projected to quadruple over the next 50 years.[4] The potential financial burden of this disease on the healthcare system could reach crisis proportions in the near future unless more effective avenues are developed to provide care for these individuals, to prevent the disease from occurring, or to slow its progression.

Seventy-five percent of care for AD patients is provided by family and friends.[4] Higher levels of home care have been associated with poorer health and higher rates of emotional stress in caregivers,

increasing the likelihood of placing patients in institutionalized care, which is considered the greatest financial cost in treating patients with AD.[4] On average, the cost of yearly nursing home care is $70,000 to $77,000 per year depending on the area of the country where care is provided.[4] Clearly, the greatest economic burden for the home-living AD patient is the time spent in caring for the patient, whereas in the nursing home the burden is the cost for others to provide care.

Economic data on the cost benefit of medications in AD are growing. Few studies provide prospective cost data from randomized controlled trials, and the data that does exist is for relatively short durations of therapy. Two clinical trials suggest that there is no benefit or disadvantage of donepezil compared to placebo in the cost of healthcare resource use.[42] There are no similar data for galantamine or rivastigmine. One cost analysis trial of memantine found that there was a trade-off between lower costs borne by the caregiver during treatment and higher drug costs borne by the patient.[43] Cost-effectiveness would be established if medications were shown to reduce the cost of care, particularly institutional care, but current randomized controlled trials have not been of sufficient duration to establish this.[42] Most estimates of cost related to AD therapy are based on pharmacoeconomic models involving extrapolation of results from short-term trials, epidemiologic data, and data on resource use in various healthcare delivery models.[87] Each analysis employs different assumptions and incorporates different aspects of cost, making comparisons across analyses difficult. Until long-term data are available, the true cost benefit of various treatment approaches remains unknown.

11 Data from current pharmacoeconomic studies in AD suggest that medication therapy may reduce costs of treating this illness; however, the true cost-effectiveness of these therapies has yet to be established. If AD treatments delay cognitive decline and time to nursing home placement, then they not only have potential economic benefit, but significant effects on the quality of life of patients and caregivers. Future studies, including prospective pharmacoeconomic trials of longer duration and more detailed cost-evaluation modeling, are needed to determine the role and benefits of pharmacotherapy on AD.

EVALUATION OF THERAPEUTIC OUTCOMES

An evaluation of therapeutic outcomes in the patient with AD begins with a thorough assessment at baseline and a clear definition of therapeutic goals. Cognitive status, physical status, functional performance, mood, and behavior all need to be evaluated before initiation of drug therapy. The clinician should interview both the patient and the caregiver to assess response to drug therapy. In evaluating response to cognitive agents, the clinician should ask questions about the patient's ability to perform daily functional tasks and about mood and behavior, as well as questions about memory and orientation. Objective assessments such as MMSE for cognition assessment and the Functional Activities Questionnaire for assessment of activities of daily living, can be used to quantify changes in symptoms and function.

Because target symptoms of psychiatric disorders may respond differently in dementia patients, a detailed list of symptoms to be treated should be documented in the pharmacotherapy plan to aid in monitoring. These could include, for example, "striking at spouse because patient believes spouse is an impostor," "verbal threats and refusal to allow clothes to be changed," and so on, as opposed to documenting vague symptoms such as "aggression" or "delusions." To make an accurate assessment of depression, multiple symptoms (e.g., sleep, appetite, and activity and interest levels) need to be assessed in addition to the patient's stated mood.

The patient should be observed carefully for potential side effects of drug therapy. The specific side effects to be monitored and the method and frequency of monitoring should be documented. Periodic assessments for drug effectiveness, side effects, compliance, need for dosage adjustment, and change in treatment should occur at least monthly. However, patients need to be treated for an adequate duration to see a therapeutic effect from a given intervention. Because the effects of cognition-enhancing medications are not great, a treatment period of several months to a year may be necessary before it can be determined whether therapy is beneficial. Cognitive effects of the drug are often noticed only as a plateauing during treatment or as deterioration following drug discontinuation. In general, cognitive agents should be continued if the patient is demonstrating no change in clinical status. However, if there is doubt, the medication can be slowly tapered and discontinued, and the patient monitored off the drug for 4 to 6 weeks to determine the need for continued therapy.

ABBREVIATIONS

Aβ: beta-amyloid peptide

AD: Alzheimer's disease

ADAS-cog: Alzheimer's Disease Assessment Scale—Cognition

Apo E: apolipoprotein E

APP: amyloid precursor protein

DSM-IV-TR: *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision

MMSE: Mini-Mental Status Examination

NFT: neurofibrillary tangle

NMDA: *N*-methyl-D-aspartate

NSAID: nonsteroidal antiinflammatory drug

SSRI: selective serotonin reuptake inhibitor

CHAPTER 64

Multiple Sclerosis

JACQUELYN L. BAINBRIDGE AND JOHN R. CORBOY

KEY CONCEPTS

1. The etiology of multiple sclerosis (MS) is unknown, and currently there is no cure.
2. Multiple sclerosis is characterized by central nervous system demyelination and axonal damage, and appears to be autoimmune in nature.
3. Multiple sclerosis is classified by the nature of progression over time into several categories which have different clinical presentations and responses to therapy.
4. Diagnosis of MS requires evidence of dissemination of lesions over time and in multiple parts of the central nervous system and/or optic nerve, and is made primarily on the basis of clinical symptoms and examination. Diagnostic criteria also allow for the use of magnetic resonance imaging, spinal fluid evaluation, and evoked potentials to aid in the diagnosis.
5. Acute exacerbations or relapses of MS can be disabling. When this is the case, acute exacerbations and relapses are treated with high-dose glucocorticoids, such as methylprednisolone, intravenously, with onset of clinical response typically within 3 to 5 days.
6. Treatment of relapsing-remitting MS with the disease-modifying therapies (DMTs) interferon β (Avonex, Betaseron, Rebif, Extavia), glatiramer acetate (Copaxone), natalizumab (Tysabri), mitoxantrone (Novantrone), and fingolimod (Gilenya) can reduce annual relapse rate, lessen severity of relapses, slow progression of changes on magnetic resonance imaging scans, slow progression of disability, and slow cognitive decline. In addition, they have been shown to reduce the likelihood of developing a second attack after a first clinically isolated syndrome consistent with MS.
7. In most cases, treatment with DMTs should begin promptly after the diagnosis of relapsing-remitting MS, or after a clinically isolated syndrome if the brain magnetic resonance imaging is suggestive of high risk of further attacks. Natalizumab, and other choices that have been associated with problematic adverse events, should be reserved for those patients who have failed one or more standard therapies and those with poor prognostic signs.
8. The definition of treatment inadequacy for relapsing-remitting MS remains unclear, and therapy changes after "treatment failure" should be individualized.
9. Although studies do not support the general use of any of the FDA-approved DMTs in patients with progressive forms of the illness, information derived from multiple studies suggests younger patients with progressive illness and those with either superimposed acute relapses or enhancing lesions on magnetic resonance imaging scans may benefit from some of the presently used DMTs.
10. Patients suffering with MS frequently have symptoms such as spasticity, bladder dysfunction, fatigue, neuropathic pain, cognitive dysfunction, and depression that can require treatment. Patients must be counseled that therapies such as interferon β and glatiramer acetate will not relieve these symptoms. Depression is common in MS and can pose the risk of suicide.

Multiple sclerosis (MS) is an inflammatory disease of the central nervous system (CNS) that affects approximately 1 in 200 women and somewhat fewer men in the United States.[1] The term multiple sclerosis refers to two characteristics of the disease: the numerous affected areas of the brain and spinal cord producing multiple neurologic symptoms that accrue over time, and the characteristic plaques or sclerosed areas that are the hallmark of the disease.

1 Although MS was first described almost 140 years ago, the cause remains a mystery, and a cure is still unavailable. Nevertheless, many advances have been made in treating and managing the complications of the disease and improving the quality of life of individuals affected by MS.

EPIDEMIOLOGY

Epidemiologic aspects of MS have been reviewed in a variety of publications.[1–5] MS usually is diagnosed in patients between the ages of 15 and 45 years, and the peak incidence occurs in the fourth decade of life. There are approximately 10,000 new cases diagnosed per year in the United States. Women are afflicted more than men by a ratio of approximately 2:1. Men usually develop the first signs of MS at a later age than women and are also more likely to develop the progressive form of the disease. The most important factors in the determination of risk for developing the disease are geography, age, environmental influences, and genetics. In general, disease prevalence is higher the greater the distance from the equator. Within the United States, the prevalence of MS is higher in states above the 37th parallel. Multiple sclerosis occurs more frequently

in whites of Scandinavian ancestry than in other ethnic groups. Epidemiologic and experimental data have suggested an inverse relationship between MS risk and 25-hydroxyvitamin D levels.[1,6]

ETIOLOGY

It is thought that genetically susceptible individuals ≤15 years of age who have lived in a high-risk area for at least 2 years and were exposed to a crucial environmental agent are at risk for developing MS. Interestingly, an individual who migrates from a low- to a high-risk area prior to the age of 15 years acquires the same chance of developing MS as those who live in a high-risk area all their lives.[2] If the move is made from a high- to a low-risk area, the individual retains the high risk if the move is made after the age of 15 years but acquires the lower risk if the move is made prior to this age.[2] Smoking cigarettes has been associated with both an increased risk of developing MS and with more severe progression of disability.[5,7]

Viral or bacterial infections may be an important environmental cause of MS. Although no clear association has been identified, infections might cause either a direct attack on myelin and the oligodendrocyte, or stimulation of an autoimmune response leading to demyelination. Evidence to support a viral etiology includes increased immunoglobulin G (IgG) synthesis in the CNS, increased antibody titers to certain viruses, and epidemiologic studies that indicate a childhood exposure factor, suggesting that "viral" infections may precipitate exacerbations. In addition, viruses have been shown to cause diseases with prolonged incubation periods, myelin destruction, and a relapsing-remitting course in both humans and experimental animal models.[1,8]

Although numerous viruses have been proposed as associated with MS, the greatest evidence is for Epstein-Barr virus (EBV). Antibody titers to Epstein-Barr nuclear antigen (EBNA) complex are higher in MS patients vs controls, especially if blood is collected ≥5 years before onset. These titers increase over time in MS patients vs controls (controls are unchanged), and a 4-fold increase in EBNA titers over time results in a 3-fold increased risk of developing MS (almost 18-fold increase in those with first samples before age 20).[9] Interestingly, one paper notes individuals positive for *HLA DRB1*1501* have a 24-fold increased risk of developing MS when they also have antibodies to certain epitopes within EBNA-1 compared with others.[10] This is consistent with a genetic-environmental interaction. In addition, anti-EBNA titers have been associated with relapsing-remitting MS (RRMS), conversion of clinically isolated syndrome (CIS) to RRMS, and with magnetic resonance imaging (MRI) measures such as gadolinium-enhancing lesions, change in T2 lesion volume (r = 0.27; P = 0.044), and Expanded Disability Status Scale (EDSS) score (r = 0.3; P = 0.035). Zivadinov et al. also found anti-EBNA and anti-vascular cell adhesion (VCA) titers associated with gray matter atrophy in MS.[11] While Serafini et al. have claimed to identify evidence of abortive infection in a significant number of MS patients,[12] others have not been able to replicate these findings.[13] The majority of the data would lead to a conclusion that exposure to EBV is somehow associated with developing MS, but does not support the concept of an active or aborting EBV infection directly causing MS.

The familial recurrence rate of MS is approximately 5%, with siblings being the most commonly reported relationship,[4] and a concordance rate among monozygotic twins of approximately 25%.[14] This is consistent with the idea that an environmental agent is important in the etiology of MS, but also suggests a role for one or more genes. Genes that lie within the major histocompatibility complex (MHC), which is located on the sixth chromosome in humans, have been linked to MS.[1,4] Recent data show a significant association of risk with mutations in the IL-2α and IL-7α receptor genes.[15,17] African Americans are significantly less likely to be diagnosed with MS compared with whites, though there is emerging evidence that they are more likely to have a severe disease course[18] and respond less well to interferon therapy.[19] A locus on chromosome 1 may be associated with increased susceptibility in African Americans.[20]

PATHOPHYSIOLOGY

2 The basic physiologic derangement in MS is the stripping of the myelin sheath surrounding CNS axons. This activity is associated with an inflammatory, perivenular infiltrate consisting of T and B lymphocytes, macrophages, antibodies, and complement.[8] Demyelination renders axons susceptible to damage, which becomes irreversible when they are severed. Irreversible axonal damage correlates with disability and can be visualized as hypointense lesions, or "black holes," on T_1-weighted MRI.[21,22]

It is now well accepted that MS lesions are heterogeneous, which may be in part due to differences in the stage of evolution of the lesions over time, differences in underlying immunopathogenesis, or a combination of the two. Briefly stated, acute lesions show demyelination and axonal destruction with lymphocytic activity consistent with an inflammatory state. In contrast, more chronic lesions display less inflammatory lymphocytes with active remyelination.[8] Although traditional descriptions have focused on the white matter as the sole location of MS lesions, more recent studies have clearly identified cortical and subcortical gray matter lesions both pathologically[23] and radiographically.[24] In addition, a subset of patients with progressive MS are noted to have abnormalities consistent with B-cell follicles in the meninges.[25]

Just as the full dimensions of the neuropathology are uncertain, so is the pathogenesis of the MS lesion. There is substantial evidence, however, to suggest it is an autoimmune process directed against myelin and oligodendrocytes, the cells that make myelin in the CNS[8] (Fig. 64–1). A new concept of T-cell entry into the CNS suggests that the initial lymphocyte invasion in MS may proceed through the ventricles, towards the choroid plexus along a CCL 20 gradient that attracts activated Th17 cells.[26] The actual mediator of myelin and axonal destruction has not been established, but may reflect a combination of macrophages, antibodies, destructive cytokines, and reactive oxygen intermediates. The exact trigger for the activation of the T cells in the periphery remains unclear, but the T cells in MS patients recognize myelin basic protein (MBP), proteolipid protein, myelin oligodendrocyte glycoprotein, and myelin-associated glycoprotein. T-helper subtypes can be either pathogenic or protective in MS. Furthermore, theory holds that certain T-cell subsets are not terminally differentiated, but instead engender a level of plasticity that allows for their conversion from pathogenic to protective and vice versa under certain conditions (Fig. 64–2).[27] In patients with stable or mild disease, increased numbers of cells are found that express messenger RNA (mRNA) for transforming growth factor-β (TGF-β) and interleukin-10 (IL-10) compared with patients with severe disease. Conversely, a reduction in the number of T-regulatory (Treg) cells, which exhibit suppressor activity, is associated with active MS and can be found in patients with progressive disease. It should be noted, however, that Treg ratios do not always correlate with disease activity. Of note, there is experimental evidence that associates high 25-hydroxyvitamin D levels with improved Treg function, favoring the Th2 phenotype in the Th1/Th2 balance.[28] Finally, the significance of one of the immunological hallmarks of MS, the intrathecal synthesis of multiple clones of immunoglobulins, remains unclear. The antigen(s) against which these immunoglobulins are directed remain unknown, but do not appear to include common CNS myelin antigens.[29] The complex interplay of a variety of cells, antibodies, and cytokines remains to be elucidated.

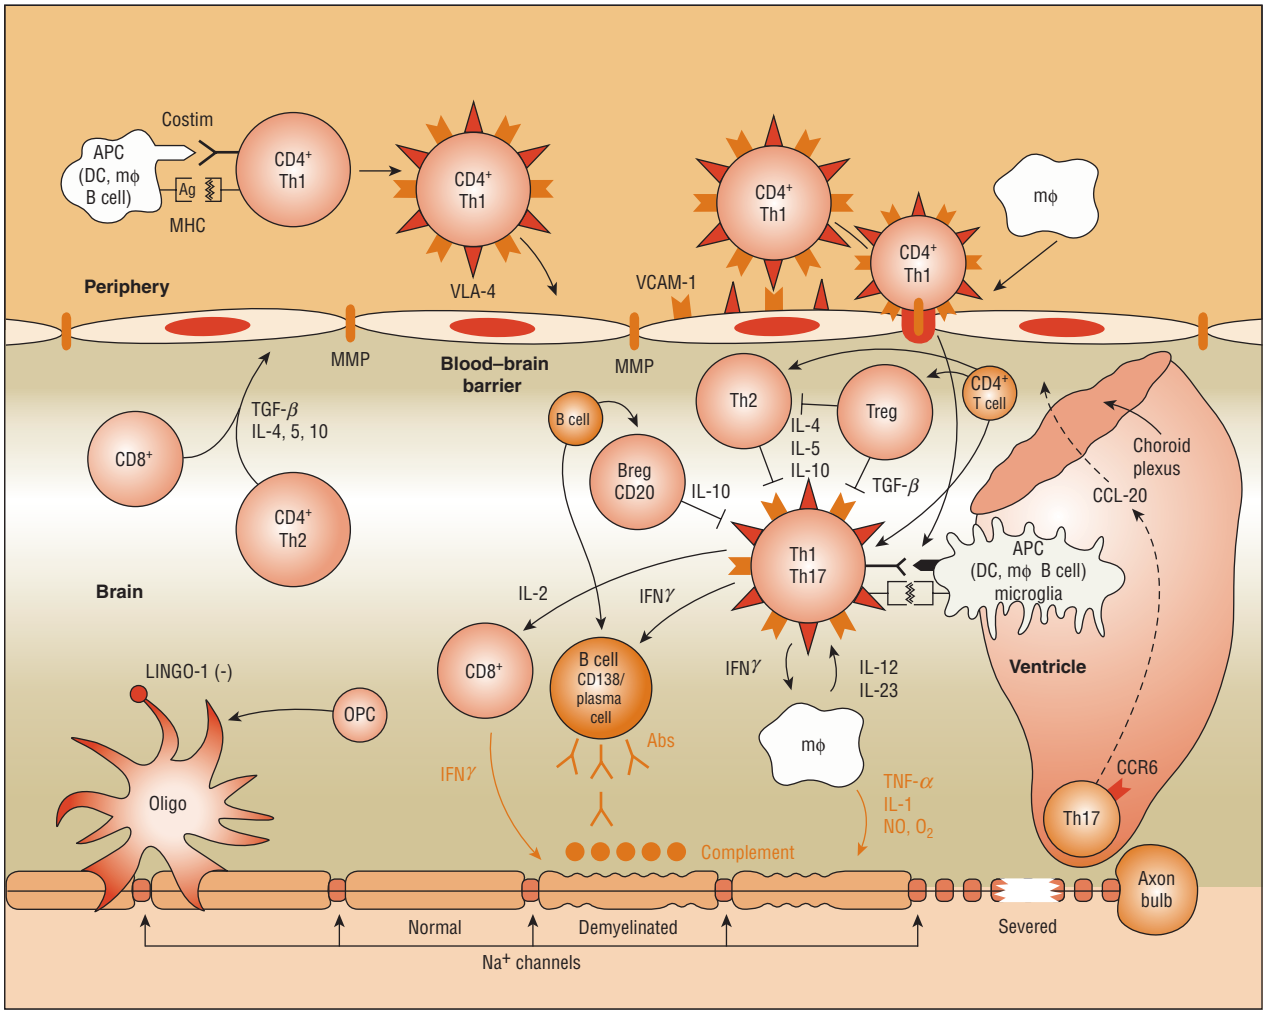

FIGURE 64-1. Autoimmune theory of the pathogenesis of multiple sclerosis (MS). In MS, the immunogenic cells tend to be more myelin-reactive, and these T-cells produce cytokines mimicking a Th1-mediated pro-inflammatory reaction. T-helper cells ($CD4^+$) appear to be key initiators of myelin destruction in MS. These autoreactive $CD4^+$ cells, especially of the T-helper cell type 1 (Th1) subtype, are activated in the periphery, perhaps following a viral infection, and express adhesion molecules on their surfaces that allow them to attach and roll along the endothelial cells that constitute the blood–brain barrier. In order for this reaction to occur, costimulation and MHC along with an antigen on an APC (macrophage, dendrite cell, B cell) must be present. The activated T cells also produce MMP that help to create openings in the blood–brain barrier, allowing entry of the activated T cells past the blood–brain barrier and into the CNS. Once inside the CNS, the T cells produce pro-inflammatory cytokines, especially interleukins (ILs) 1, 2, 12, 17, and 23, tumor necrosis factor-α (TNF-α), and interferon-γ (INF-γ), which further create openings in the blood–brain barrier, allowing entry of B cells, complement, macrophages, and antibodies. The T cells also interact within the CNS with the resident microglia, astrocytes, and macrophages, further enhancing production of proinflammatory cytokines and other potential mediators of CNS damage, including reactive oxygen intermediates and nitric oxide. The role of modulating, or downregulating, cytokines such as IL-4, IL-5, IL-10, and transforming growth factor-β (TGF-β) also has been described. These cytokines are the products of $CD4^+$, $CD8^+$, and Th1 cells.[8] New pathogenic mechanisms involve, but are not limited to, receptor-ligand mediated T-cell entry via choroid plexus (CCR6-CCL20 axis),[26] coupling of key receptor-ligands for inhibition of myelination/demyelination (LINGO-1/NOGO66/p75 or TROY complex, Jagged-Notch signaling). (Ag, antigens; APC, antigen presenting cell; DC, dendrite cell; IgG, immunoglobulin G; Mϕ, macrophage; NA^+, sodium ion; MMP, matrix metalloproteinases; MHC, major histocompatibility complex; OPC, oligodendrocyte precursor cell; VLA, very late antigen; VCAM, vascular cell adhesion molecule.)

CLINICAL PRESENTATION OF MULTIPLE SCLEROSIS

General

- Most patients with multiple sclerosis present with nonspecific complaints. Many have problems with their vision or paresthesias.

Primary Symptoms/Signs

- Visual complaints/optic neuritis
- Gait problems and falls
- Paresthesias
- Pain
- Spasticity
- Weakness
- Ataxia
- Speech difficulty
- Psychological changes
- Cognitive changes
- Fatigue
- Bowel/bladder dysfunction
- Sexual dysfunction
- Tremor

Laboratory Tests

- MS is a diagnosis of exclusion
- Magnetic resonance imaging
- Cerebrospinal fluid studies
- Evoked potentials

Secondary Symptoms

- Recurrent urinary tract infections
- Urinary calculi
- Decubiti and osteomyelitis
- Osteoporosis
- Respiratory infections
- Poor nutrition
- Depression

Tertiary Symptoms

- Financial problems
- Personal/social problems
- Vocational problems
- Emotional problems

CLINICAL CONTROVERSY

A small but significant number of patients have been identified who have not had clear MS symptoms, but MRI scans, typically done for purposes other than to look for signs of MS, have identified what appear to be typical lesions consistent with MS. Patients may then have further changes on MRI scans, again with no clinical signs. Similarly, a significant percentage of patients with established MS will have MRI changes unassociated with new clinical signs. It is unclear whether MRI changes in isolation should trigger a clinician to begin or alter therapy.

CLINICAL PRESENTATION AND COURSE OF ILLNESS

3 The clinical presentation of MS is extremely variable among patients and typically varies over time in a given patient. The signs and symptoms of MS can be divided into three categories. Primary symptoms are a direct consequence of conduction disturbances produced by demyelination and axonal damage and reflect the area

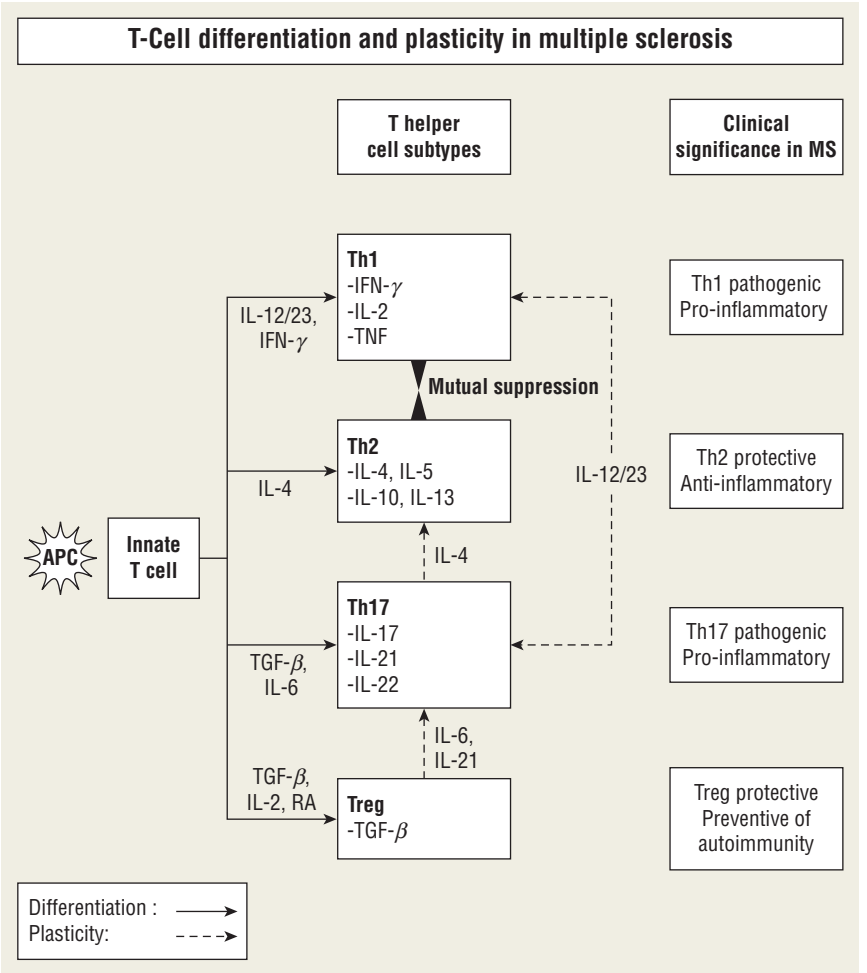

FIGURE 64-2. Upon interaction with an antigen-laden APC and specific cytokines, the innate T-cells undergo differentiation into a few lineages (subtypes). Four subtypes significant for MS pathophysiology are illustrated here (Th1, Th2, Th17, Treg). Th1 and Th17 are pro-inflammatory, Th2 is antiinflammatory, and Treg is regulatory. Th1 and Th2 are mutually suppressive and are relatively stable differentiated subtypes. In contrast, Th17 and Treg subtypes are recently found to exhibit "plasticity." In other words, they can undergo phenotypic conversion to another T-cell subtype (Th1 or Th2) in the presence of specific cytokine conditions. This plasticity of Th17 and Treg is the immunologic basis for development of therapeutic agents to favor the production of suitable Th subtypes for combating microbial invasion and also concurrently achieving neurocellular recovery after an infection.[27] (APC, antigen presenting cell.)

of the brain or spinal cord that is damaged. Secondary symptoms are complications resulting from primary symptoms. For example, urinary retention, a primary symptom, can lead to frequent urinary tract infections, a secondary symptom. Tertiary symptoms relate to the effect of the disease on the patient's everyday life.[30]

The clinical course of MS is classified into four categories.[31] At the onset of symptoms, about 85% of patients have attacks—new symptoms lasting at least 24 hours and separated from other new symptoms by at least 30 days—followed by remissions (complete or incomplete). Attacks frequently are referred to as relapses or exacerbations, and the first attack is called a clinically isolated syndrome. This course is called relapsing-remitting MS. During the RRMS phase, there is a correlation between new brain MRI lesions and clinical attacks, but typically there are many more new MRI lesions than new clinical symptoms. In RRMS patients, attack frequency tends to decrease over time and becomes independent of the development of progressive disabilities.[32] Neurologic recovery following an acute exacerbation is often quite good early in the disease course, but following repeated relapses, recovery tends to be less complete. In addition, there is a new concept of a radiologically isolated syndrome (RIS), referring to individuals who have clinical scenarios not typical of MS, yet obtain MRI scans for other reasons (e.g., headache) and have radiological signs suggestive of MS. Some percentage of these patients convert to typical MS over time,[33] although when to start treatment remains unclear.

Up to 10% to 20% of RRMS patients have a benign course, characterized by few relapses, often sensory, with minimal disability accruing over time. Most RRMS patients eventually enter a progressive phase in which attacks and remissions generally are difficult to identify. This is referred to as secondary-progressive MS (SPMS). Disability tends to accumulate more significantly during this phase of the illness. New brain MRI lesions, especially those seen only after the injection of contrast material, are less common, and brain atrophy and T1 holes increase.[34]

Approximately 15% of patients never have acute attacks and remissions but have progressive disease from the outset, known as primary-progressive MS (PPMS). These patients will have symptoms, especially spastic paraparesis, that may worsen rapidly or relatively slowly over time, and they accrue progressively more disability. Patients with PPMS are diagnosed at a later age, and the number of males is roughly equal to that of females. In general, PPMS patients tend to have a worse prognosis than those who present initially with RRMS, although more recent data suggest progression is variable.[35] Many clinical trials have suggested that a significant portion of patients with PPMS do not receive benefit from studied therapies. However, a recent article using rituximab suggests a subgroup of PPMS patients who are less than 51 years of age and have at least one gadolinium-enhancing lesion may benefit from this therapy.[36] Finally, a small percentage of patients may have a mixture of both progression and relapses, referred to as progressive-relapsing MS (PRMS). These are generally treated as relapsing patients.

Progression of the illness throughout the lifetime of the individual can be measured in many ways. The most widely used clinical rating scale in MS is the EDSS, which uses a numerical value ranging from 0 (no disability) to 10 (death from MS) to evaluate several neurologic functions.[37] The limitations of this scale are the relative insensitivity to clinical changes not involving impairment of gait and ambulation, such as changes in cognition, fatigue, and affect. Other tools, such as the Multiple Sclerosis Functional Composite (MSFC), are being evaluated for possible increased sensitivity and utility in describing changes in MS-related disability over time.[38] Increasingly, MRI is being used as an index of both disease activity and progression.[8] Specifically, the appearance of new lesions or changes in lesion number, size, and volume are being used as outcome measures in research studies. Optical coherence tomography measures the retinal neural fiber layer thickness, and may also be a measurable sign of pathological progression over time.[39]

TABLE 64-1 Prognostic Indicators in Multiple Sclerosis

Indicator	Favorable Prognosis	Unfavorable Prognosis
Age at onset	<40 years	>40 years
Gender	Female	Male
Initial symptoms	Optic neuritis or sensory symptoms	Motor or cerebellar symptoms
Attack frequency in early disease	Low	High
Course of disease	Relapsing/remitting	Progressive

Data from Swanson,[42] McDonald et al.,[43] and Polman et al.[44]

The unpredictable nature of MS makes it impossible to anticipate when an exacerbation will occur. However, certain factors may aggravate symptoms or lead to an acute attack (new episode of demyelination), including infections, heat (including fever), sleep deprivation, stress, malnutrition, anemia, concurrent organ dysfunction, exertion, and childbirth. Interestingly, many patients experience a significant reduction in acute relapses during the third trimester of pregnancy, followed by a relative increase postpartum.[40]

Multiple sclerosis usually does not directly diminish life expectancy. The development of secondary complications such as pneumonia or septicemia (secondary to aspiration of mouth contents with swallowing difficulties, decubitus ulcers, or urinary tract infections) or rapid progression of primary lesions affecting respiratory function can lead to a shorter than expected life span. Most of this decrease in life span is seen in patients with rapidly progressive disease. Suicide rates as high as 7 times that expected in the general population have been reported.[41] Clinical and demographic factors used to predict prognosis of MS are listed in Table 64–1.[5,42] Several MRI features also have been shown to correlate with progression of disease (see below).[44–46]

DIAGNOSIS

4 Multiple sclerosis is a diagnosis of exclusion; symptoms frequently can be attributed to other neurologic diseases, just as many syndromes can mimic MS. Some patients may have typical symptoms consistent with classic CIS, whereas many others may have symptoms that are more vague. The diagnosis remains primarily a clinical one that requires the demonstration of "lesions separated in space and time," referring to the occurrence of at least two episodes of neurologic disturbance reflecting distinct sites of damage in the CNS that cannot be explained by another mechanism.[43] An international panel of MS experts was convened in 2000 to reevaluate current diagnostic criteria and to incorporate new data. The result of this panel's work is the McDonald criteria,[43] which allow brain MRI lesions, cerebrospinal fluid (CSF) abnormalities, and visual-evoked potential (VEP) studies to substitute for clinical lesions in defining "separated in space and time." A recent reevaluation of the McDonald criteria has simplified the use of these laboratory studies.[44] In the new scheme, diagnostic categories are MS, possible MS (for those individuals at high risk of developing MS), and not MS. The new criteria allow for earlier diagnosis.[47] Newer, simpler MRI criteria defining dissemination in time and space may be somewhat more sensitive and equally specific.[48,49] A consensus panel of the American Association of Neurology endorses the utility of MRI for diagnostic purpose,[47] and the U.S. Food and Drug Administration (FDA) has approved several of the immunotherapies to be used after a single attack of demyelination in the context of an appropriately abnormal brain MRI.

LABORATORY STUDIES

To date, there are no tests specific for MS. Evidence provided by MRI of the brain and spine, CSF evaluation, and evoked potentials, used in conjunction with the physical examination and history, aids in establishing the diagnosis of MS.

Imaging Studies

MRI produces images of the brain and spine that reflect damage in the CNS that is characteristic of MS plaques in multiple forms, for instance, in the periventricular white matter areas of the brain, as well as more generalized abnormalities such as brain atrophy. MRI is the preferred technique and is much more sensitive than computed tomography. It is useful for establishing diagnosis and prognosis. Patients with a single, typical attack of demyelination (possible MS or CIS, e.g., optic neuritis) and three or more T_2-weighted lesions on the brain MRI have an almost 90% likelihood of developing a second attack (clinically definite MS) over 15 years.[45] Optic neuritis is a common first symptom of MS and is indicative of a lesion or lesions localizing on the optic nerve. In contrast, similar individuals with normal brain MRIs have only a 19% likelihood of developing MS over 15 years.[45] Total volume of T_2-weighted lesions (called *T_2 burden of disease*) at the onset of CIS also appears to correlate with the development of disability.[45] Lesions that enhance after injection of the contrast material gadolinium indicate new lesions and disruption of the blood—brain barrier and are associated with early conversion to MS in CIS/possible MS patients,[45] but do not correlate well over time with progression of disability. Brain atrophy, even early in the course of the illness, probably correlates better with progression of disability.[46]

CSF Evaluation

In MS patients, CNS synthesis of IgG is increased, whereas serum IgG levels are normal. IgG synthesis rate, or the so-called IgG index, both of which compare the amount of IgG in the CSF to that in blood as normalized to overall protein counts, are typically elevated. Electrophoretic studies of the CSF show that the IgG separates into a small number of discrete bands, which, when similar bands are not seen in the serum samples taken at the same time, are called *oligoclonal bands* (OCBs).[50] Oligoclonal banding (the presence of five or more oligoclonal bands) of IgG is present in 90% to 95% of patients with clinically definite, established MS but also may be seen in lower percentages of diseases that mimic MS or are quite different clinically.[50] Increasingly, with advances in MRI, CSF analysis is reserved only for patients with atypical clinical scenarios or individuals with possible MS in whom a CSF positive for OCBs may help to define a more definite diagnosis of MS. Although white blood cell counts are often slightly elevated in the CSF of MS patients, the presence of greater than 50×10^6/mL (50×10^9/L) mononuclear cells in the CSF usually indicates a diagnosis other than MS.[50]

Evoked Potentials

Evoked potentials may be helpful in establishing areas of demyelination that are clinically silent. Slowed conduction of visual, brainstem, and somatosensory potentials can be identified, although the sensitivity and specificity of these tests seem to be somewhat less than that seen with MRI or CSF evaluation. Newer diagnostic criteria allow only for the use of VEPs to aid in formal diagnosis.[43,44]

Blood Studies

A recent report has suggested that in CIS patients with abnormal brain MRIs and abnormal CSF consistent with MS, presence or absence of antimyelin antibodies in serum may be helpful in defining prognosis for further events consistent with clinically definite MS.[51] The utility of this test, if any, remains to be defined.

DIFFERENTIAL DIAGNOSIS

A number of disorders can mimic MS. Thus, most patients are screened with blood tests for rheumatologic, collagen-vascular, infectious, and sometimes inherited metabolic diseases. Magnetic resonance imaging may rule out tumors and cervical spondylosis. The use of MRI has led to evaluations for MS in many patients with little or no clinical history consistent with MS; while some of these patients may have MRI scans suggestive of MS (so-called RIS), most of these patients have nonspecific MRI scans with identifiable causes for their scan abnormalities, including age greater than 50 years, hypertension, and migraine.[52] There are many causes of nonspecific lesions seen in the subcortical white matter on a brain MRI, and use of established criteria for distinguishing MS lesions from other etiologies enhances diagnostic accuracy. Electromyography may help in diagnosing amyotrophic lateral sclerosis and neuropathies.

TREATMENT

Treatment of MS falls into three broad categories: symptomatic therapy, treatment of acute attacks, and disease-modifying therapies (DMTs) to alter the natural course of the disease. Symptomatic management of the disease is of utmost importance to maintain the patient's quality of life. Treatment of acute attacks will shorten the duration and possibly decrease the severity of the attack. Disease-modifying therapies that alter the course of the illness are most important to diminish progressive disability over time.

A number of different treatment modalities have been studied in the last 30 years, but many older trials had flawed designs. There are no universally accepted treatment algorithms, and treatments vary among clinicians and centers. Perhaps more importantly, treatment decisions frequently are based on the wishes and goals of individual patients. One potential algorithm for the immunotherapy of RRMS is shown in Figure 64–3.

CLINICAL CONTROVERSY

When patients initially show signs of RRMS, many practitioners begin treatment with IFN-β or glatiramer acetate (ABC-R medications). However, it is controversial which medication to use, and when to start. Most data support minimal, if any, differences in efficacy among the ABC-R medications. The role of natalizumab remains unclear, but under 10% of natalizumab prescriptions have been for patients who have never used the ABC-R medications. The introduction of fingolimod further complicates the issue. Most practitioners assist newly diagnosed patients in making the decision of which medication best fits their lifestyle and offers the maximum efficacy. In patients with severe depression, interferon therapy is contraindicated, and patients are encouraged to use glatiramer acetate.

TREATMENT OF ACUTE EXACERBATIONS

5 Mild acute exacerbations that do not produce functional decline may not require treatment. When functional ability is affected, the standard intervention is intravenous injection of high-dose corticosteroids. The American Academy of Neurology recommends that if treatment with steroids is warranted, it is best to use intravenous methylprednisolone.[53] The mechanism of action for corticosteroids in MS is unknown, but it is speculated that steroids improve recovery by decreasing edema in the area of demyelination.

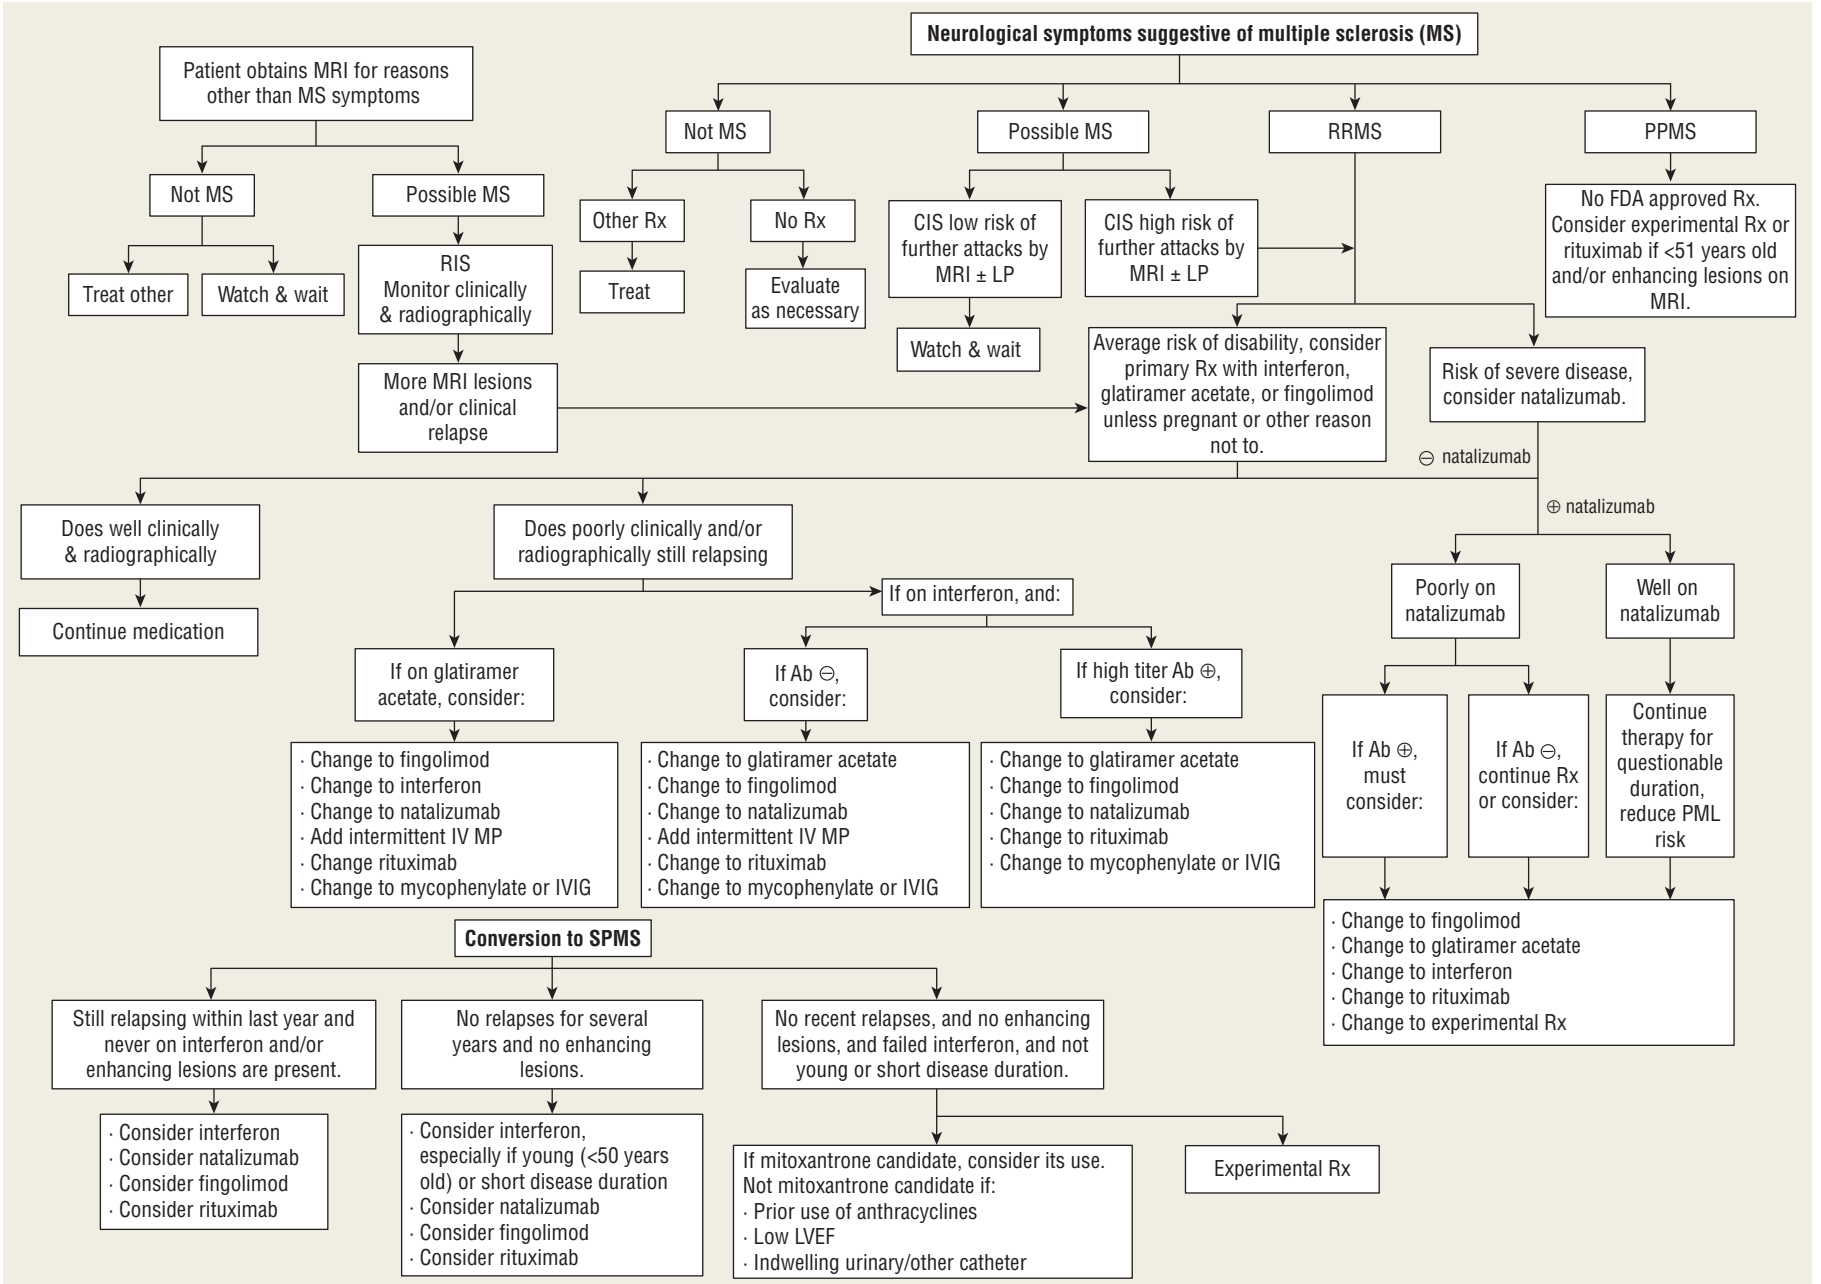

FIGURE 64-3. An algorithm for management of relapsing-remitting multiple sclerosis. (ABC-R, interferon β_{1a} [Avonex], interferon β_{1b} [Betaseron], glatiramer acetate [Copaxone], and interferon β_{1a} [Rebif]; IVIg, intravenous immunoglobulin.)

Intravenous methylprednisolone has been shown to shorten the duration of acute exacerbations, and it may delay repeat attacks for up to 2 years after optic neuritis,[53] although it has not been shown definitively to affect the progression of disease.[54] More recently, many practitioners are using high doses of oral methylprednisolone, especially mixing the lyophilized powder in flavored drinks such as smoothies, but there are no comparative data to define this as an equivalent way to deliver the medication.

Methylprednisolone doses can range from 500 to 1,000 mg/day, given intravenously. The duration of therapy is variable and can range from 3 to (rarely) 10 days, depending on clinical response. If improvement occurs, it usually begins to be seen after 3 to 5 days. Short-term use of this nature is often accompanied by sleep disturbance, a metallic taste, and, rarely, gastrointestinal upset. Patients with diabetes mellitus or a predilection to diabetes mellitus may have significant elevations of blood sugar, requiring the use of insulin. Longer durations of intravenous methylprednisolone therapy are associated with acne and fungal infections, mood alteration and, rarely, gastrointestinal hemorrhage (especially if used in hospitalized patients or those taking aspirin concurrently). If methylprednisolone is not available, equipotent doses of dexamethasone have been used as a substitute, although not well supported in the literature.

A very small number of patients have more severe attacks, manifested by hemiplegia, paraplegia, or quadriplegia. If these patients fail to improve with aggressive steroid therapy, plasma exchange every other day for seven treatments can be beneficial for approximately 40% of patients.

DISEASE-MODIFYING THERAPY

Interferon β_{1b} and Interferon β_{1a}

6 Interferon (IFN)-β_{1b} (Betaseron) was the first agent proven to favorably alter the natural course of the illness.[55] In Table 64–2, disease-modifying therapies are listed with evidence-based recommendations from the American Academy of Neurology.[55] Although the exact mechanism of action is unknown, IFN-β_{1b}'s effect in MS may be caused by its immunomodulating properties, including the ability to augment suppressor cell function and reduce IFN-γ secretion by activated lymphocytes, its macrophage-activating effect, and its ability to downregulate the expression of IFN-γ-induced class II MHC gene products on antigen-presenting glial cells. Interferon also suppresses T-cell proliferation and may decrease blood—brain barrier permeability.[55] IFN-β also increases the production of regulatory CD56 (bright) natural killer cells and Treg cells.[56] In general, all interferons exert these actions in the periphery and at the blood—brain barrier level. Interferons work at the blood—brain barrier level by decreasing matrix metalloproteinases.

Interferon β_{1b} is a nonglycosylated synthetic analog of recombinant IFN-β and is produced in *Escherichia coli*. Interferon β_{1b} is administered subcutaneously every other day at a dose of 250 mcg (8 million international units). Clinical trials have demonstrated that at these doses, IFN-β_{1b} significantly reduces annual relapse rate and MRI burden of disease compared with placebo. With respect to clinical disability, however, no significant differences were noted between the interferon- and placebo-treated groups.[55] Betaseron is packaged in partially premixed syringes with a new formulation that does not require refrigeration and can be used with an autoinjector. Betaseron costs approximately $19,632 per year. In 2009, an additional interferon product was introduced into the market under the trade name Extavia. Extavia is the same medicinal product as Betaseron.

Interferon β_{1a} (Avonex and Rebif) is a natural-sequence glycosylated interferon produced in Chinese hamster ovary cells. Avonex is given as 30 mcg (6 million international units) intramuscularly once weekly. The prefilled syringes (33 mcg/0.5 mL, 4 per package) should be refrigerated, but can be kept at room temperature for 30 days. Avonex costs approximately $18,360 per year. Rebif is made in a very similar fashion as Avonex but given as either 22 or 44 mcg (0.5 mL) subcutaneously 3 times weekly. It is supplied in a 0.5-mL prefilled syringe with an autoinjector and costs approximately $21,163 per year. Rebif should also be kept refrigerated, but it is stable at room temperature for 30 days. A new formulation may have lower immunogenicity and a slightly better side-effect profile.[57]

When given 30 mcg intramuscularly once weekly for 2 years, patients receiving IFN-β_{1a} (Avonex) demonstrated, compared with placebo, statistically significant reductions in annual relapse rate (by approximately one-third) as well as disease progression, which was defined as a confirmed decrease of 1 point on the EDSS.[75] Disease progression also was assessed by MRI studies, and patients receiving active drug had significantly fewer new enhancing lesions compared with placebo-treated patients. Similar results were seen with higher dose (44 mcg), more frequent administration (3 times weekly), and subcutaneous injection of IFN-β_{1a} (Rebif).[55] Other

TABLE 64-2 Evidenced-Based Recommendations for Disease Modifying Treatment of Multiple Sclerosis

Recommendations	Recommendation Grades[a]
Interferon β	
• Interferon β has been shown to reduce attack rates in patients with MS or those with CIS who are at high risk of developing MS	A-I
• It is appropriate to consider IFN-β for any patient with clinically definite MS or who already has RRMS or SPMS and is still experiencing relapses	A-I
• The effectiveness of IFN-β in patients with SPMS but without relapses is uncertain	U-I
• Route of administration of IFN-β products is probably not clinically important with regards to efficacy; however, the side effect profile does differ	B-II
• Rate of production of neutralizing antibodies is probably less with IFN-β_{1a} than with IFN-β_{1b}	B-I
• Presence of neutralizing antibodies may be associated with a reduction in the clinical effectiveness of IFN-β treatment	C-I
Glatiramer acetate	
• Glatiramer acetate has been shown to reduce the attack rate in patients with RRMS	A-I
• Treatment with glatiramer acetate may slow sustained disability progression in RRMS	C-I
Mitoxantrone	
• Mitoxantrone probably reduces the attack rate in patients with relapsing forms of MS	B-II, III
• Mitoxantrone may have a beneficial effect on disease progression in MS	C-II, III
Natalizumab	
• Natalizumab decreases clinical relapse rate, Gd – enhancing lesions, and new T2 lesions	A-I
• Natalizumab in RRMS positively changes measures of disease severity such as EDSS progression rate and changes lesions on MRI in RRMS	A-I

CIS, Clinically isolated syndrome; RCT, randomized controlled trial; RRMS, relapsing-remitting MS; SPMS, secondary-progressive MS.

[a]Strength of recommendations: A: established. B: probable. C: possible. U: inadequate data to support recommendation.

Quality of evidence: Class I, evidence from one or more prospective, randomized, controlled clinical trial; Class II, evidence from cohort or RCT not meeting criteria for class I; Class III, evidence from other controlled trials; Class IV, Evidence from uncontrolled studies, case reports, case series or expert opinion.

studies reveal significant effects on slowing brain atrophy[58] and the progression of cognitive decline[59] in patients treated with Avonex. Taken together, these observations show that IFN-β possesses significant disease-modifying activity.

Side effects are similar with all the interferons. Baseline complete blood counts, platelet determinations, and liver function tests should be documented before starting therapy, at 1 month, then every 3 months for 1 year, and every 6 months thereafter. Small percentages of patients develop depressed cell counts and liver enzyme elevations that are usually transient and respond to discontinuation of therapy. Rare patients have developed true liver failure requiring liver transplant, and the package inserts for interferon β products have been altered, reflecting this risk. The most common adverse effects include injection-site redness, swelling, and, rarely, necrosis, as well as flu-like symptoms (e.g., fever, chills, myalgias). These symptoms can be mild or severe and are seen in most patients. The flu-like side effects typically occur for up to 24 hours after injection and typically abate within 1 to 3 months after starting the injections, but they persist in some patients. Injection-site reactions probably are worse with IFN-β_{1b}, can occur at any time, and can be lessened by using appropriate injection technique, including site rotation (thighs and buttocks), hydrocortisone cream, applying ice before and after the injection, or use of an autoinjector. Injecting the medications at body temperature (place under armpits) will decrease injection-site pain. Nonsteroidal antiinflammatory agents or acetaminophen taken before and at regular intervals for 24 hours after administration may alleviate the flu-like symptoms. Initiation of one-quarter or one-half the standard dose, and then increasing to full dosage over 1 to 2 months, also may be beneficial in reducing flu-like side effects.[60] Some authors suggest that, because of the transient immune activation that can occur following the introduction of IFN-β, a short burst of oral prednisone can alleviate some adverse effects.[60]

Less commonly reported side effects include shortness of breath, tachycardia, thyroid dysfunction, and depression. Clinicians must monitor patients carefully for signs of depression and treat accordingly. Although depression is a common finding in MS patients, all the interferons, especially IFN-β_{1b}, can produce depressive symptoms. Patients who develop depression should be monitored closely because of the risk for suicide. Other side effects usually are transient. Most patients will not feel better or have improvement in symptoms when taking interferons, and many will experience side effects; thus compliance can become a major issue. Finally, safety data on IFN-β in pregnancy and lactation are lacking. Abortifacient activity in primates has been noted, and until adequate safety data are available, women should be counseled as to appropriate contraception while using these products.

Although the adverse-effect profile of IFN-β_{1a} resembles that of IFN-β_{1b}, intramuscular IFN-β_{1a} (Avonex) may hold several advantages, including fewer local injection-site reactions and once-weekly administration versus subcutaneous injection every other day (or 3 days per week with Rebif).

Glatiramer Acetate (Copaxone)

Glatiramer acetate (Copaxone, formerly known as copolymer-1) is a synthetic polypeptide consisting of L-alanine, L-glutamic acid, L-lysine, and L-tyrosine. Although the precise mechanism of action of this compound is unknown, glatiramer acetate appears to mimic the antigenic properties of MBP.[61] This agent also may act by directly binding to MHC class II receptors and inhibiting binding of MBP peptides to T-cell receptor complexes.[61] Glatiramer acetate has demonstrated that it induces Th2 (antiinflammatory) lymphocytes in experimental allergic encephalomyelitis.[61] This is thought to contribute to "bystander" suppression at the site of the MS lesion and thereby reduce inflammation, demyelination, and axonal damage.[55] Glatiramer acetate also may suppress T-cell activation, and recent studies suggest it may be associated with a neuroprotective effect by inducing brain-derived neurotrophic factor.[62]

Given as a daily 20-mg subcutaneous dose, glatiramer acetate appears to have a relatively mild adverse effect profile. Mild pain and pruritus at the injection site are the most frequent patient complaints. Approximately 10% of patients experience a one-time transient reaction consisting of chest tightness, flushing, and dyspnea beginning several minutes after injection and lasting usually no longer than 20 minutes. If patients have no history or evidence of coronary artery disease, they may be assured these reactions are almost always self-limited and benign. Several adverse effects that have been associated with the interferons, including flu-like symptoms and depression, do not appear to be provoked by glatiramer acetate. Multicenter trials with glatiramer acetate have demonstrated significant reductions in mean annual relapse rate (approximately 29%) that are comparable with the interferons.[55] An extension trial, completed after the original, pivotal 2-year study, suggests that glatiramer acetate may slow the progression of disability in patients with RRMS.[55] Glatiramer acetate also slows development of T_1 holes on brain MRIs,[63] and long-term uncontrolled data show that it remains safe and effective for individuals who continue to take it over 10 years.[64] The annual cost of glatiramer acetate is approximately $19,749 (20 mg/mL in 30 prefilled syringes). The product is stored in the refrigerator but can be kept at room temperature for up to 1 week.

CLINICAL CONTROVERSY

Because of the potential for progressive multifocal leukoencephalopathy (PML), controversy surrounds the proper selection of patients for natalizumab therapy. With the apparent superior efficacy of natalizumab compared to other disease-modifying therapies, many clinicians use natalizumab as a primary agent in selected individuals with RRMS who are identified with poor prognostic signs such as multiple early relapses, severe relapses with incomplete remission, and MRI markers of poor prognosis, such as high burden of disease on T_1 and T_2 images, or early signs of atrophy. Whether to restrict the use of natalizumab to a maximum number of months, or alter the dosing, in an effort to limit the risk of PML, remains unclear. Prior exposure to chemotherapy appears to increase risk of PML. The advent of a serology study for JC Virus exposure may alter clinicians' willingness to prescribe natalizumab as a first line agent or alter the duration that they prescribe it.

Natalizumab (Tysabri)

Natalizumab is a partially humanized monoclonal antibody directed at the cell surface adhesion molecule $\alpha_4\beta$-integrin (also known as very-late antigen 1, VLA-1). Natalizumab works by attaching to VLA-1 and blocking its interaction with its ligand on CNS endothelium vascular cell adhesion molecule (VCAM)-1. Thus, activated lymphocytes are denied entry past the blood—brain barrier. In a phase II study, compared to placebo, natalizumab significantly reduced the number of new gadolinium-enhancing lesions by more than 90%, and diminished relapses as well.[65] In a 2-year phase III trial (A Randomized, Placebo-Controlled Trial of Natalizumab for Relapsing Multiple Sclerosis [AFFIRM]), compared to placebo, annual relapse rate was reduced by more than 60%, gadolinium-enhancing lesions were lessened by more than 90%, and progression of disability was significantly delayed.[66] In a separate 2-year, phase III trial (The Safety and Efficacy of Natalizumab in Combination with

Interferon Beta-1a in Patients with Relapsing Remitting Multiple Sclerosis [SENTINEL]) in patients already taking IFN-β_{1a} (Avonex), those who had natalizumab added to IFN-β_{1a} had a relapse rate reduction of more than 50% and gadolinium-enhancing lesion reduction of 84% compared to patients who continued with IFN-β_{1a} alone.[67] In these trials, natalizumab was injected intravenously every 4 weeks and was relatively well tolerated, although approximately 1% of patients developed infusion reactions, and 6% developed neutralizing antibodies that diminished the efficacy of the drug.

On November 23, 2004, the FDA approved natalizumab, with the stipulation that the studies would continue, for use in relapsing MS in patients with inadequate response or intolerance to other MS therapies. In February 2005, Biogen and Elan voluntarily removed natalizumab from the market after receiving reports of two patients (one patient from the SENTINEL trial, and one patient in a Crohn's disease study), who both died after developing progressive multifocal leukoencephalopathy (PML), a rare brain infection most commonly seen in patients infected with human immunodeficiency virus.[68–70] One other patient who developed PML in the SENTINEL trial survived.[68–70] Further safety analysis did not identify other cases, and on March 9, 2006, an FDA panel reviewing the data suggested reapproval of natalizumab for use in relapsing patients who would be required to be placed in an ongoing safety registry (TOUCH). On June 5, 2006, the FDA reapproved use of natalizumab in the United States, with a black-box warning about PML. Since that time, over 71,000 patients around the world (roughly 50% in the United States) have been exposed to natalizumab for treatment of MS. As of September 2010, 68 cases of PML have been identified, all in patients using the medication for 12 months or longer. The incidence for developing PML is 1 in 1,000, though it tends to increase the longer a patient is on the drug. Plasma exchange (PLEX) has been utilized to help clear the drug more rapidly from the blood of affected patients.[91] An acute syndrome referred to as immune reconstitution inflammatory syndrome has been associated with acute neurological deterioration after PLEX, requiring the use of steroids.[72] Also in 2009, natalizumab has been approved for use in Crohn's disease.

Natalizumab is indicated as monotherapy, 300 mg every 4 weeks as an IV infusion. It is indicated for the relapsing forms of MS to delay the accumulation of physical disability and decrease the number of relapses in patients who have a documented inadequate response or intolerance to traditional MS therapies. The cost of natalizumab is approximately $31,200 annually (300 mg/15 mL), which does not include nursing and other fees.[73] Patients receiving natalizumab must be enrolled in the TOUCH program. In the future, patients' blood and CSF may be screened at baseline and every 6 months to assess the presence of JC and BK virus DNA.[74]

Fingolimod (Gilenya)

Approved September 21, 2010, fingolimod is the first oral DMT for MS. It has a unique mechanism of action as a sphingosine 1-phosphate receptor agonist. Fingolimod exhibits its immunosuppressant properties by sequestering circulating lymphocytes into secondary lymphoid organs and reduces the infiltration of T-lymphocytes and macrophages into the CNS. It may have neuroprotective effects. The agent is given daily at a dose of 0.5mg. In clinical trials it decreased annualized relapse rates by approximately 52% compared to interferon beta-1a. After 5 years of continuous fingolimod therapy, approximately 92% of patients were free of gadolinium enhancing lesions, though these data were with the 1.25 mg dose. Major side effects include pronounced first dose bradycardia and, rarely, bradyarrhythmia or atrioventricular block, infections, macular edema, a decrease in forced expiratory volume over 1 second, elevation of liver enzymes, and a sustained increase of approximately 1 to 2 mm Hg in systolic and diastolic blood pressure. Rare cases of lymphoma have also been identified. The reversal of lymphopenia can take 2 to 4 weeks after discontinuation of the drug. Monitoring recommendations include baseline complete blood counts, liver function tests, ophthalmologic examinations, and electrocardiogram in patients with known heart problems. At the time of the first dose, baseline pulse and blood pressure must be taken, and the patient must be observed for 6 hours, although the monitoring setting may be individualized. The degree to which fingolimod's oral delivery may alter the likelihood of a patient using, or continuing to use, a self-injectable medication remains to be seen.

Mitoxantrone

7 Mitoxantrone (Novantrone), a member of the anthracenedione family, is approved by the FDA for reducing neurologic disability and the frequency of clinical relapses in patients with SPMS (chronic), PRMS, or worsening RRMS.[75] The MRI outcomes, however, were not as robust as those typically seen in the trials of relapsing patients alone.[76] Mitoxantrone is administered as a brief (5- to 15-minute) intravenous infusion dosed at 12 mg/m^2 every 3 months. An evaluation of left ventricular ejection fraction and electrocardiogram are required prior to administration of each dose and if signs or symptoms of congestive heart failure develop. The maximum allowable lifetime cumulative dose of mitoxantrone is 140 mg/m^2. Other potential side effects noted with this agent are nausea, alopecia, menstrual disorder, amenorrhea, upper respiratory tract infection, urinary tract infection, and leukemia. The role mitoxantrone will ultimately play in the treatment of MS remains unclear because potential cardiac toxicity limits its long-term use. More recent estimates also suggest the risk of leukemia may be as high as 1 in 145 patients, which has significantly decreased interest in its use for MS patients.[77] In addition, although patients with SPMS were included in the mitoxantrone in MS (MIMS—Effect of Mitoxantrone on MRI in Progressive MS) trial, resulting in FDA approval for use in SPMS, there was no substudy documenting slowing of progression specifically in this subgroup of patients.[75,76] Thus, support for use of mitoxantrone in this context is less strong.[55] The average wholesale cost of mitoxantrone is approximately $1,982 (average male) or $1,586 (average female) per infusion and will vary based on the patient's body surface area. Nursing, pharmacy, and technical fees must also be added to this estimate.

CLINICAL CONTROVERSY

Many RRMS patients have either been intolerant to, failed to respond to, or been unwilling to undergo the risk associated with all of the FDA-approved medications. There are some data supporting the use of a variety of agents which have been approved for other purposes, such as rituximab and mycophenylate. When to incorporate off-label uses of medications remains a controversy.

REMAINING QUESTIONS FOR DISEASE-MODIFYING THERAPY

8 Despite encouraging results from well-conducted clinical trials, several relevant issues remain. The most important question in the use of the DMTs is when to begin therapy. The Medical Advisory Board of the National Multiple Sclerosis Society has adopted recommendations regarding the use of the current MS DMTs (Table 64–3).[78]

Decisions about the use of any medication rest on determination of the severity of the illness, the efficacy of the medication, and the side effects and costs related to the therapy. Clearly,

TABLE 64-3 Disease Management Consensus Statement

- Initiation of therapy with an IFN-β medication (Avonex, Betaseron, Rebif, Extavia) or glatiramer acetate is advised as soon as possible following a definite diagnosis of MS with active, relapsing disease, and can also be considered for selected patients with a first attack who are at high risk of MS.
- Natalizumab is FDA approved for patients who have had an inadequate response to, or are not able to tolerate other MS therapies.
- Mitoxantrone can be considered for patients with relapsing worsening disease or patients with secondary-progressive MS who are worsening, whether or not relapses are occurring.
- Patients' access to medication should not be limited by the frequency of relapses, age, or level of disability.
- Treatment is not to be stopped during evaluation for continuing treatment.
- Therapy is to be continued indefinitely, unless there is clear lack of benefit, intolerable side effects, new data that reveal other reasons for cessation, or better therapy becomes available.
- Interferon βs (Avonex, Betaseron, Rebif, Extavia), glatiramer acetate (Copaxone), mitoxantrone (Novantrone), and natalizumab (Tysabri), are all FDA approved for patients with MS and should be included in formularies and covered by third-party payers so that physicians and patients can determine the most appropriate agent on an individual basis.
- Movement from one immunomodulating drug to another should be permitted for medical reasons.
- None of these agents are approved for use in women trying to become pregnant, who are pregnant, or nursing mothers.

Data from Miller et al.[78] with permission.

these drugs slow the course of the illness but do not suppress it completely, and in some individuals, there is no apparent benefit. There is now, however, overwhelming evidence that the vast majority of untreated patients will have progressive disease over time. Pathologic data clearly show that even in acute lesions there is significant axonal damage that is essentially irreversible. MRI data show that 80% to 90% of all new enhancing lesions are asymptomatic, suggesting that a "quiet" clinical course does not necessarily mean there is not ongoing disease activity that ultimately will be reflected in cognitive problems and progressive spastic paraparesis.

Furthermore, it is now known that very early therapy is effective. In patients with CIS and two or more T_2 lesions on brain MRI (i.e., at high risk for developing clinically definite MS), placebo-controlled studies with all three of the interferon agents and glatiramer acetate have shown significant delay in a second attack and positive outcomes on a variety of MRI measures (BENEFIT = Betaseron in Newly Emerging Multiple Sclerosis for Initial Treatment; CHAMPS = Controlled High Risk Subjects Avonex Multiple Sclerosis Prevention Study; and ETOMS = Early Treatment of Multiple Sclerosis).[55,79] Thus, very early therapy is potentially warranted, and IFN-β_{1b}, IFN-β_{1a} (Avonex), and glatiramer acetate are approved by the FDA for use after CIS in those patients with abnormal MRIs consistent with demyelination, suggestive of high risk of further demyelinating events. The National Multiple Sclerosis Society recommends that patients with relapsing disease should be placed on Avonex, Betaseron (or Extavia), Copaxone, or Rebif (ABC-R) therapy immediately after the diagnosis.[78]

A second major issue is which drug to use in which patient. There has not been a single, randomized study comparing all four ABC-R drugs with one another in a similar patient population at the same time.[80] The pivotal placebo-controlled trials produced results that were more similar than different when comparing across trials, including a nearly identical one-third reduction in relapse rate for all four drugs over 2 years. A small number of studies have suggested higher dose, more frequent administration of interferon may be more efficacious than lower dose, less frequent administration,[81,82] but these differences appear modest. Other studies argue against this,[83,84] and recent studies note no significant difference in outcomes between standard and double dose IFN-β_{1b} and glatiramer acetate,[85] and no difference between IFN-β_{1a} (Rebif) and glatiramer acetate.[86]

A concern with all three interferon products that further muddies our understanding of the clinical differences between the interferon products is the development of neutralizing antibodies. In clinical trials, 30% to 40% of patients receiving IFN-β_{1b} developed antibodies directed against the drug.[87] In these patients, the exacerbation rate was similar to that in placebo-treated patients. In patients on IFN-β_{1b}, neutralizing antibodies can occur first at 3 to 6 months and as late as 18 months. This product tends to be the most antigenic.[87] With IFN-β_{1a}, neutralizing antibodies were found in 22% of early trials of Avonex, but later studies reported that only 2% to 5% of treated patients developed antibodies; this decrease was caused by a formulation change of the drug making it the least antigenic.[84,87] Percentages for Rebif are intermediate, therefore moderately antigenic, at approximately 12% and can occur in the first 9 to 15 months of treatment, which is the same time frame for antibody production with Avonex.[55,87,88] The long-term clinical significance of these findings, however, is still not completely clear, although three recent studies have further confirmed the effect of neutralizing antibodies on relapses, MRI lesions, and progression of disability.[88–91] Whether these antibodies are truly cross-reactive between products is unknown, as is the duration during which antibodies can be detected. There are no general consensus guidelines regarding when to test for neutralizing antibodies, which assay to use, or what titer cutoff to apply to patients in clinical settings.[92] An important question is whether production of antibodies might be diminished with treatments such as corticosteroids. Another concern of practitioners is the relationship between active ingredients and varying excipients of interferon therapies and the production of neutralizing antibodies. Neutralizing antibodies are seen in approximately 6% of patients treated with natalizumab, and the antibodies seem to diminish efficacy.[67]

9 We now have experience for more than a decade with MS patients taking DMTs, yet continuing to have more relapses, more lesions on MRI, more disability, and ongoing slippage into SPMS.[93] There is no accepted definition of treatment inadequacy, although the Canadian Multiple Sclerosis Research Council has suggested a relatively simple approach that incorporates the elements of relapse rate, new MRI lesions, and change on the EDSS.[94] If a patient develops significant and persistent interferon antibodies, movement to a noninterferon (glatiramer acetate, natalizumab, fingolimod, mitoxantrone, or possibly rituximab[95]) is reasonable. When failing low-dose interferon, options include changing to a higher dose, more frequent administration of interferon, or changing to a noninterferon. A second option is addition of an immunosuppressant agent, such as monthly methylprednisolone,[96] azathioprine, methotrexate, or mycophenolate. As noted above, the addition of natalizumab to IFN-β_{1a} was effective, but produced rare cases of PML, and thus, this combination should not be used. The addition of a statin agent may worsen MS[97] although these results are not definitive.

SYMPTOMATIC MANAGEMENT

10 Many of the symptoms of MS do not require pharmacologic management or do not respond to it. This section addresses the primary symptoms in which pharmacologic management may be of benefit (Table 64–4).[30,94,98–100] See the preceding section on the treatment of acute exacerbations for a discussion of optic neuritis.

Gait Difficulties and Spasticity

Problems with gait can be caused by spasticity, weakness, ataxia, defective proprioception, or a combination of these factors. Spasticity

TABLE 64-4 Treatment of Selected Primary Multiple Sclerosis Symptoms

Spasticity	Bladder Symptoms	Sensory Symptoms	Fatigue
Baclofen	Propantheline	Carbamazepine	Amantadine
Dantrolene	Oxybutynin	Phenytoin	Antidepressants
Diazepam	Dicyclomine	Amitriptyline or other TCAs	Modafinil
Tizanidine	DDAVP	Gabapentin	Methylphenidate
Tiagabine	Self-catheterization	Lamotrigine	Dextroamphetamine
Gabapentin	Imipramine or amitriptyline	Pregabalin	
Pregabalin	Prazosin		
Botulinum toxin type A	Botulinum toxin type A		
Dalfampridine	Solifenacin		
	Darifenacin		
	Trospium		
	Hyoscyamine		
	Fesoterodine		

DDAVP, desmopressin acetate; TCA, tricyclic antidepressant.
Data from Schapiro,[30] Freedman et al.,[94] Mitchell,[98] Goodman et al.,[99] Kinn and Larson.[100]

is amenable to pharmacologic intervention, whereas physical therapy may be required in treating gait disturbances owing to any of the other factors. Spasticity is encountered commonly and tends to affect the legs more markedly than the arms. Spasticity can result in falls; however, in the later stages of the disease, the increased muscle tone of a spastic limb often lends strength to patients with underlying weakness. Therefore, when using muscle relaxants, one must be careful not to decrease the tone to an extent that ambulation is actually hindered.[30,98] Baclofen (Lioresal), a γ-aminobutyric acid (GABA) analog, is the preferred agent and usually is started in dosages of 10 mg 3 times daily and titrated upward to achieve the desired response. Most patients achieve a satisfactory response with dosages between 40 and 80 mg/day; however, dosages higher than the recommended daily maximum of 80 mg are required by some patients.[30,98] A wearing-off is common, however, due to the relatively short duration of action. A longer-acting version of Lioresal is under study. Continuous intrathecal administration of baclofen may be an option for patients unable to tolerate or unresponsive to oral therapy. Baclofen should not be discontinued abruptly to avoid the possibility of seizures.[98] Small doses of diazepam (Valium) (e.g., 0.5–1 mg) often are added to baclofen in patients in whom optimal response has not been achieved.

Another effective agent with a different mechanism of action is tizanidine (Zanaflex). This short-acting, α-adrenergic agonist acts in the CNS to reduce spasticity by increasing presynaptic inhibition of motor neurons. It appears to have efficacy comparable with that of baclofen.[98] Dosage must be titrated slowly over 2 to 4 weeks, starting with 4 mg at bedtime, with adjustments based on clinical response. Effective tolerated dosages have ranged from 2 to 36 mg/day. Sedation, dizziness, and dry mouth are the most commonly reported adverse effects, but hypotension also can occur, as well as a rare but severe hepatotoxicity. Tizanidine can be added in small dosages to baclofen, sometimes resulting in better results and smaller doses of each drug.

In patients who are unable to tolerate baclofen or tizanidine, diazepam (Valium; 2–10 mg/day), clonazepam (Klonopin; 1–3 mg/day), or dantrolene sodium (Dantrium; 100–400 mg/day), may be considered as alternatives, but they generally are less effective than either baclofen or tizanidine. Mild spasticity also may respond to moderately high doses of gabapentin (Neurontin; 1,800–3,600 mg/day). Tiagabine (Gabitril 8–56 mg/day) may be useful in some patients with spasticity, but side effects can prohibit its use. Pregabalin (Lyrica; 75–300 mg/day) has similar features and mechanism of actions as gabapentin, although pregabalin is approximately 3 times more potent and does not saturate the L-system transporter system in the gastrointestinal system, so it may prove useful in the treatment of spasticity in MS patients.

Botulinum toxin type A (Botox; dose depending on the muscles injected) has been shown to be effective in improving spasticity.[30] The amount of toxin required to exert an effect on spasticity is often too excessive to use safely in the larger muscles; therefore, its use is best limited to smaller areas of focal muscle spasm.

An alternative approach to gait disruption employs K^+ channel blockers such as 4-aminopyridine (4-AP). Recent studies have shown that 4-AP may modestly improve walking speed.[99] In early 2010, the FDA approved the use of a long-acting proprietary version of 4-AP, dalfampridine (Ampyra; 20mg/day), for use in the United States.

Tremor

Cerebellar symptoms such as tremor can be troubling and difficult to control. Medications that can be helpful include propranolol, primidone, and isoniazid.

Bowel and Bladder Symptoms

Patients commonly complain of incontinence, urgency, frequency, and nocturia, which are indications of a hyperreflexic bladder (i.e., inability to store urine). A number of anticholinergic agents, including oxybutynin chloride (Ditropan; 10–20 mg/day), tolterodine (Detrol; 2–4 mg/day), propantheline bromide (Pro-Banthine; 45–90 mg/day), hyoscyamine (Levsin; 0.75–1.5 mg/day), and dicyclomine hydrochloride (Bentyl; 30–80 mg/day) are used to treat this problem if symptoms are mild. Ditropan is now also available in an extended-release formulation (5 and 10 mg). In addition, tricyclic antidepressants, such as imipramine (Tofranil) and amitriptyline (Elavil), have been used for their anticholinergic properties. With all anticholinergic agents, great care must be used to avoid the problem of constipation, which is worsened by the patient's natural instinct to limit fluid intake (owing to the increasing urge to urinate). Newer medications include antimuscarinic agents such as trospium chloride (Sanctura; 40 mg/day), solifenacin succinate (Vesicare; 5–10 mg/day), darifenacin hydrobromide (Enablex; 7.5–15 mg/day), and fesoterodine (Toviaz; 4–8 mg/day). As an alternative, the synthetic antidiuretic hormone preparation desmopressin acetate (DDAVP; 0.2–0.6 mg/day) has been reported to be effective in the treatment of urgency and incontinence.[98] Use of DDAVP probably is best limited to bedtime so as to improve sleep and because there can be significant problems with hyponatremia and possible seizures if overused. Patients with significant sphincter dyssynergia may benefit from the oral use of α-adrenergic blockers such as prazosin (Minipress; 10–40 mg/day) or intramuscular use of botulinum toxin type A (Botox; dose depends on the muscles injected).

Intermittent self-catheterization with or without a concomitant anticholinergic agent is recommended in patients with large postvoid urine residual volumes (greater than 100 mL) or when the urinary problem is hyporeflexic in nature (failure to empty). Patients with large postvoid residual volumes are at risk for developing urinary tract infections (UTIs) and often are prescribed urinary acidifiers such as vitamin C or antiseptics such as methenamine mandelate to prevent infections. Antibiotics used for UTI prophylaxis include sulfamethoxazole/trimethoprim, cephalexin, cinoxacin, and nitrofurantoin.

Constipation is the most common bowel complaint. Many medications (narcotics, anticholinergics) in common use may worsen this problem, as may voluntary water restriction in those patients with urinary urgency and incontinence. Increases in dietary fiber

and hydration may alleviate this problem, but in some instances laxatives or enemas may be necessary.

Major Depression

Major depression is common in patients with MS, and the risk of suicide may be increased markedly compared with healthy subjects.[101] Patients should be monitored closely for the development of major depressive symptomatology and treated accordingly (see Chapter 77). Interferon products and natalizumab should be used cautiously in patients with significant depression.

Sensory Symptoms

Numbness and paresthesia are frequent sensory complaints but usually do not require treatment. Some MS patients may develop acute or chronic pain syndromes[98] such as trigeminal neuralgia and painful dysesthesias, for which treatment is necessary. Carbamazepine (Tegretol; 400–1,200 mg/day) is the preferred agent for the treatment of trigeminal neuralgia. Other agents also commonly used for neuropathic pain include amitriptyline and related tricyclic antidepressants, gabapentin, pregabalin, and duloxetine.

Sexual Dysfunction

Sexual dysfunction in both men and women are common in MS, and counseling should be offered to both partners. Sildenafil citrate (Viagra), tadalafil (Cialis), and vardenafil (Levitra) are very effective for men with MS who have erectile dysfunction. Other options for men include alprostadil injection (Caverject) or intraurethral suppositories (MUSE). Viagra is currently being studied in females with MS and sexual dysfunction. In patients needing antidepressant therapy for whom sexual dysfunction is a concern, bupropion is preferable to selective serotonin reuptake inhibitors as it has a much lower incidence of sexual side effects.

Fatigue

Fatigue, one of the most common complaints in MS patients, can be severely disabling, but treatment is often overlooked. Typically present in the mid to late afternoon, it can increase with heat exposure, exertion, intercurrent infection, spasticity, weakness, and depression. Amantadine hydrochloride (100 mg twice daily) is used often and may offer significant relief.[30,94] Methylphenidate (Ritalin) and related products, and dextroamphetamine (Dexedrine) are used commonly for fatigue in MS. Modafinil (Provigil), at 100 mg twice daily, is also helpful for MS-related fatigue. In patients suffering from both depression and fatigue, a more activating antidepressant such as fluoxetine may be employed.

Cognition

Cognitive dysfunction is common in MS, affecting up to 50% or more of patients. It generally manifests itself as word finding difficulties and problems with concentration and short term memory. Cognitive dysfunction can be treated with stimulants or cholinesterase inhibitors.

COMPLEMENTARY AND ALTERNATIVE THERAPIES FOR MS

A large percentage of patients with MS use complementary and alternative medicine (CAM) instead of, or in addition to, disease-modifying and symptomatic therapies. Common CAM therapies include diet and dietary supplements, such as vitamins, minerals, and herbs. Antioxidant supplements vitamin A, C, E, α-lipoic acid, coenzyme Q10, grape seed, pine bark extracts, mangosteen and acai have suggestive evidence of benefiting MS patients. However, for patients with MS, there is a theoretical risk involved with taking antioxidant supplements owing to their ability to stimulate the immune system (T cells and macrophages). Stimulating the immune system in patients with MS could be counterproductive, possibly worsening or exacerbating their disease, and may counteract the effects of immunomodulators. Other immune-stimulating supplements that should be used with caution are garlic, ginseng (Asian and Siberian), echinacea, cat's claw, astragalus, alfalfa, and stinging nettle. A few agents that may pose a problem in MS, but may have benefit when taken in moderation, are zinc, melatonin (for insomnia), and dehydroepiandrosterone.[102]

In general, there are insufficient data supporting the effectiveness and safety of CAM therapies for MS. However, for patients with MS who are willing to try new approaches with limited evidence, CAM may be a consideration in some cases. Healthcare providers can be a source of objective information regarding the use of CAM for MS and can assist their patients in making the best decision.[102]

INFLUENZA VACCINE RECOMMENDATIONS

A yearly flu shot is recommended for all patients with MS, including patients on any of the DMTs. The intranasal influenza vaccine, FluMist, which is a live, attenuated vaccine, is not recommended for patients with MS, however. As DMTs suppress the immune system, a patient taking one of these medications is at increased risk for developing an infection of the strain of virus given in the vaccine. Live virus vaccines are also more likely to cause an increase in MS disease activity than inactivated virus vaccines. Finally, it is unknown whether there are any direct interactions between DMTs and the intranasal influenza vaccine.[103] This information can likely be extrapolated to other vaccines, so if a patient is in need of a vaccination of any kind, "killed" virus vaccines are recommended.

Patients opting to take fingolimod who are varicella zoster virus antibody negative should consider receiving the varicella zoster virus immunization (even though it is a live attenuated vaccine) at least one month prior to beginning fingolimod. This should allow time to mount an antibody response prior to immunosuppression with fingolimod.

PHARMACOECONOMIC CONSIDERATIONS

As with many therapeutic decisions, economic cost, both to the individual and to society, must be considered. Currently, the annual cost of the DMTs is considerable. The *Red Book* average wholesale price (used for all products in this chapter) of each of the currently available interferons is between $18,300 and $21,200 per patient per year. Given this expense, it must be remembered that these therapies are not curative and that individual patients may experience variable results. Future investigations evaluating these therapeutic modalities clearly will need to address not only clinical but also economic and humanistic outcomes.

A recent cost-benefit analysis has identified that even more expensive therapies, such as natalizumab, may be cost-effective due to their ability to more effectively reduce the likelihood of relapses, thus resulting in lower treatment costs and hospitalization for acute relapses.[104]

EVALUATION OF THERAPEUTIC OUTCOMES

Response to treatment of acute exacerbations of MS is commonly seen within days. With respect to DMTs, it is important for the clinician to recognize that over the short term (days to weeks), little or no apparent benefit may be noted by either patient or

clinician. Evaluation of therapeutic outcomes, such as decreased MS exacerbations and hospitalizations or perhaps slowed disease progression and disability (as measured using scales such as EDSS), must be conducted over a period of months to years. Patients should be provided with realistic goals and expectations of these treatment options and encouraged to participate in the evaluation of therapeutic response. Initially, it may be important to reevaluate patients at relatively short time intervals to monitor for adverse effects.

Safety monitoring of patients on interferon includes regular laboratory monitoring, patient observation, and questioning for adverse effects or changing disability, and regular neurologic examinations. Specific laboratory monitoring for individuals on interferon therapy should include a complete blood count, platelet count, and liver function tests. These should be completed at baseline, every 3 months for 1 year, and every 6 months thereafter. Glatiramer acetate requires no laboratory monitoring. In addition to counseling patients regarding the adverse effects associated with these drugs, pharmacists should actively encourage patients to comply with their prescribed regimens.

CONCLUSIONS

Multiple sclerosis is an inflammatory disease of the CNS that strikes young, genetically susceptible individuals living in high-risk geographic areas. Although the exact etiology of MS is unknown, it is likely that MS is an autoimmune disease triggered by an as yet undetermined environmental agent or agents. There is no cure, but quality of life can be improved through symptomatic management, and the disease course is partially suppressed by presently available DMTs.

ACKNOWLEDGMENT

The authors acknowledge the contributions of Michael Egeberg, PharmD, May Wong, PharmD, Nora Li, PharmD, and Joan Kaufman, illustrator, for their contributions to this chapter.

ABBREVIATIONS

4-AP: 4-aminopyridine

ABC-R: Avonex, Betaseron, Copaxone, and Rebif

CAM: complementary and alternative medicine

CIS: clinically isolated syndrome

CNS: central nervous system

CSF: cerebrospinal fluid

DDAVP: desmopressin

DMT: disease-modifying therapy

EBV: Epstein-Barr virus

EDSS: expanded disability status scale

FDA: Food and Drug Administration

GABA: γ-aminobutyric acid

HLA: human leukocyte antigen

IgG: immunoglobulin G

IL-2: interleukin-2

IL-10: interleukin-10

MHC: major histocompatibility complex

MBP: myelin basic protein

MRI: magnetic resonance imaging

MS: multiple sclerosis

MSFC: Multiple Sclerosis Functional Composite

OCBs: oligoclonal bands

PML: progressive multifocal leukoencephalopathy

PPMS: primary-progressive multiple sclerosis

PRMS: primary-relapsing multiple sclerosis

RIS: radiologically isolated syndrome

RRMS: relapsing-remitting multiple sclerosis

SPMS: secondary-progressive multiple sclerosis

TGF-β: transforming growth factor-β

UTI: urinary tract infection

VCAM: vascular cell adhesion molecule

VEP: visual evoked potential

VLA-1: very late antigen 1
